Bleeding from the dialysis puncture site can occur hours after a hemodialysis treatment, either spontaneously or after inadvertent minor trauma to the site. Such bleeding can usually be stopped by applying firm pressure to the access site. Care should be taken not to occlude and possibly cause thrombosis of the vessel by compressing it too vigorously, and the presence of a thrill immediately after the procedure should be documented in the chart. It may be necessary to keep the patient in the ED for a time to ensure that bleeding does not recur. Recurrent bleeding, especially from an aneurysm or a pseudoaneurysm, is best evaluated by a vascular surgeon.

Similarly, if the patient reports that the thrill in the access has been lost, a vascular surgeon is consulted immediately. Although thrombolytic agents are generally used, definitive treatment is usually surgical revision. The access device should not be forcefully manipulated or irrigated because rupture of the vessel or venous embolization may result.

Infection of the vascular access can result in persistent or recurrent bacteremia, as well as loss of the access. Infection appears to be a consequence of contamination at the time of puncture for dialysis; most infections are caused by staphylococci typical of skin flora. Infections are more likely to occur in grafts than in native fistulae. The signs and symptoms of an access infection—redness, warmth, and tenderness over the site—often are obvious, but in many cases localizing findings are absent, and the patient has only fever or a history of recurrent episodes of fever and documented bacteremia. For this reason, it is common practice to obtain blood cultures for all patients on hemodialysis who have a fever without an obvious source of infection and to treat them presumptively for an access infection. A careful search for other sources of infection is performed before an apparent access infection is concluded to be the cause. Infections such as odontogenic abscess, extremity cellulitis (particularly in diabetics), and perirectal abscess can easily be missed.

Although some nephrologists prefer to admit all dialysis patients with fever to the hospital, management of these patients on an outpatient basis often is possible, provided that they otherwise feel well and do not appear to be septic and provided that they can care for themselves at home and return promptly if their condition worsens. This course is made more practicable by the fact that they can be loaded with IV antibiotics that dependably maintain adequate blood levels until the next scheduled dialysis treatment, at which time the culture and sensitivity test results can be checked and therapy adjusted accordingly. IV vancomycin, 1 to 1.5 g, given as a single loading dose, is the drug of choice in this case because most access infections are staphylococcal and because this drug is only minimally hemodialyzable and needs to be given only every 5 to 7 days in the chronic dialysis patient. If a gram-negative infection also is thought to be likely, as in a patient who has had recent episodes of gram-negative bacteremia, a loading dose of a second drug (eg, a third-generation cephalosporin or aminoglycoside) also can be administered. Patients can be reloaded with these drugs at the end of their next hemodialysis session if culture results prove to be positive.

**Non–Vascular Access–Related Complications**

The hemodialysis procedure itself, which entails invasion of the vasculature, anticoagulation, and significant shifts of fluid and solutes, often is associated with acute complications such as hypotension, shortness of breath, chest pain, and neurologic abnormalities.

**Hypotension.** Hypotension that occurs after dialysis is usually the result of an acute reduction in circulating intravascular volume and failure of the patient’s homeostatic mechanisms to compensate for it. Because hemodialysis is episodic, each treatment must remove the excess fluid that has accumulated over the period since the last dialysis (generally, 2–3 days), and patients often are relatively volume-overloaded at the beginning of each treatment. With rapid removal of extracellular fluid, there is inadequate time for transcellular fluid shifts to replace intravascular volume. Antihypertensive medications that are required when the patient is in a volume-expanded state, particularly β-blockers, can contribute to the hypotension when intravascular volume is normalized.

Most episodes of hypotension that occur during hemodialysis resolve spontaneously or can be readily managed by a decrease in blood flow rate or infusion of small volumes of saline (to cause transient volume expansion) or hypertonic solutions (to reverse transient acute hypo-osmolality). Patients with significant hypotension who do not respond to these maneuvers often are brought to the ED for further evaluation. Patients on dialysis should be considered to be at risk for acute myocardial infarction, acute dysrhythmias, and sepsis. These are common causes of hypotension among all patients in the ED, and consideration should first be given to these entities (Box 87.10).

Acute blood loss is another consideration when a hemodialysis patient presents with hypotension, symptomatic angina, or CHF. Dialysis patients are commonly treated with epoetin or darbepoetin to prevent severe anemia; untreated patients typically have low baseline hemoglobin levels. Serum levels of clotting factors are normal in CKD, but patients are routinely anticoagulated for each hemodialysis treatment and, although transient thrombocytopenia may occur during the dialysis procedure, the qualitative platelet defect characteristic of renal failure is an important factor in bleeding that continues beyond the peridialytic period. This abnormality is only partially reversed by dialysis but can be corrected by the administration of desmopressin (DDAVP), which increases the release of factor VIII–von Willebrand factor polymers from vascular endothelium. DDAVP has been used successfully to normalize the bleeding time in preparation for surgery in patients with CKD. Cryoprecipitate and conjugated estrogen both have been shown to produce similar effects for a longer period.

Occult bleeding from the GI tract, often caused by angiodysplasia or peptic ulcer disease, is common and can be dramatic. Occult
Emergency pericardiocentesis must occasionally be performed in the ED to relieve acute tamponade, but there often is enough time for the patient to be transported to the catheterization suite in the ED to relieve acute tamponade, but there often is enough time for the patient to be transported to the catheterization suite. If immediate pericardiocentesis is believed to be necessary, the emergency clinician should not hesitate to perform this potentially lifesaving procedure, despite the many potential complications and increased risk of bleeding in patients with CKD. Similarly, in the case of a dialysis patient who is in cardiac arrest, pericardiocentesis generally should be attempted if initial resuscitative efforts have not been successful.

Severe life-threatening hyperkalemia, although unusual in a dialyzed patient, can occur in the presence of underlying catabolic illness or with a prolonged period of hypotension and low flow. Patients who are hyperkalemic can have profoundly slow heart rates, particularly if they have been treated with β-blockers or calcium channel blockers. If a dialysis patient is in cardiac arrest, it should be assumed that hyperkalemia is present, and IV calcium should be given immediately.

**Shortness of Breath.** Shortness of breath in dialysis patients generally is caused by volume overload. In the patient who becomes short of breath while being dialyzed, however, other causes must be sought—primarily sudden cardiac failure, pericardial tamponade, pleural effusion, or pleural hemorrhage. Air embolism and anaphylactoid reactions are unusual causes. Often, pneumonia or underlying reactive airway disease is responsible.

**Chest Pain.** Cardiovascular disease is a leading cause of death in patients with CKD, and most episodes of chest pain occurring during dialysis are likely to be ischemic in origin. Most dialysis patients have risk factors for coronary artery disease, related to CKD itself or the underlying condition that led to renal failure, and many have well-documented coronary artery disease. CKD is commonly associated with hypertension, hyperlipidemia, carbohydrate intolerance, and disturbances of calcium and phosphorus metabolism. In addition, dialysis patients may be anemic, and many are chronically volume-overloaded. During hemodialysis, these underlying factors may be added to acute physiologic stresses such as transient hypotension and hypoxemia, which often are associated with the dialysis procedure, thereby increasing myocardial oxygen demand while decreasing oxygen delivery.

In evaluating presumed ischemic chest pain in a patient with CKD, reversible precipitants should be considered. It should be determined whether increasing anemia, poorly controlled hypertension, or uncorrected volume overload are factors, particularly when a patient whose angina has been stable begins to experience more frequent or more severe anginal episodes. Patients who repeatedly experience chest pain during dialysis are candidates for a complete cardiac evaluation. Dialysis patients who have repeated ED visits for chest pain should have a coordinated strategy developed by their nephrologist and cardiologist to set guidelines regarding further admissions.

The presence of renal failure and its associated electrolyte and acid-base disturbances does not in general obscure the usual electrocardiographic changes of angina or acute myocardial infarction. The pattern of change of serum cardiac enzyme levels with acute infarction also is not altered by CKD, although the baseline level of these enzymes may be higher than in the general population. Troponin appears to perform best as a marker of infarction in patients with CKD. Treatment of ischemic chest pain is the same as for other populations.

Among nonischemic causes of chest pain, pericarditis should always be a consideration, even in the well-dialyzed patient. The presentation is essentially the same as in nonrenal patients; fever, a friction rub, or atrial dysrhythmias may be associated findings, and signs of pericardial effusion or early tamponade should be sought. Indomethacin often is effective in relieving pain, but some patients eventually require further measures, such as pericardiocentesis with corticosteroid instillation or pericardial stripping. Patients with pericarditis often receive more frequent or intensified dialysis because pericarditis is thought to be a marker for inadequate dialysis.
**BOX 87.11**

**Differential Diagnosis of Altered Mental Status in Dialysis Patients**

**STRUCTURAL CONDITIONS**
- Cerebrovascular accident (particularly hemorrhage)
- Subdural hematoma
- Intracerebral abscess
- Brain tumor

**METABOLIC CONDITIONS**
- Disequilibrium syndrome
- Uremia
- Drug effects
- Meningitis
- Hypertensive encephalopathy
- Hypotension
- Postictal state
- Hyponatremia or hypernatremia
- Hypercalcemia
- Hypermagnesemia
- Hypoglycemia
- Severe hyperglycemia
- Hypoxemia
- Dialysis dementia

**Neurologic Dysfunction.** Neurologic dysfunction manifesting during or immediately after hemodialysis may be caused by disequilibrium syndrome, a constellation of symptoms and signs thought to result from rapid changes in body fluid composition and osmolality during hemodialysis. It usually occurs only in patients with high BUN levels who are just starting hemodialysis and osmolality during hemodialysis. It usually occurs only in patients with high BUN levels who are just starting hemodialysis; the syndrome does not occur with peritoneal dialysis. Typically, patients have headache, malaise, nausea, vomiting, and muscle cramps but, in more severe cases, features may include altered mental status, seizures, or coma. Symptoms resolve over several hours as fluid and solutes are redistributed across cell membranes.

Altered mental status in the CKD patient should not be attributed to disequilibrium syndrome unless other causes have been ruled out (Box 87.11), particularly when symptoms persist, fluctuate, or worsen during a reasonable period of observation. Likewise, when seizures occur during dialysis, it is tempting but unwise to attribute them to disequilibrium syndrome without considering other, potentially serious causes, even in patients who have had seizures in the past. In particular, the finding of any new focal neurologic abnormality calls for, at a minimum, an immediate head CT scan to detect intracranial hemorrhage. Similarly, if fever or other evidence of infection is present, meningitis must be a serious consideration. Other considerations include hyperglycemia and hypoglycemia, especially in the diabetic patient, electrolyte abnormalities, hypoxic states, hypotension of any cause, and other toxic or metabolic causes. The treatment of seizures in patients with CKD is essentially the same as for other populations.

**Peritoneal Dialysis**

As with hemodialysis, most of the complications of peritoneal dialysis are related to the dialysis access device, in this case the peritoneal catheter. In contrast to hemodialysis, however, the dialytic process in peritoneal dialysis occasions few immediate difficulties.

Peritonitis is the most common complication of peritoneal dialysis. Fortunately, it is generally much less severe than other types of peritonitis and can be treated readily on an outpatient basis, despite the continued presence of a foreign body—the Tenckhoff catheter—in the peritoneal cavity. Occasionally, when an episode of peritonitis responds poorly to antimicrobial therapy or when a patient has repeated episodes of peritonitis caused by the same organism, the catheter must be removed and the patient sustained with hemodialysis until the infection is completely cleared and a new catheter can be placed. Repeated infections carry the risk of permanently altering peritoneal permeability or effective surface area and necessitating a permanent switch to hemodialysis.

Peritonitis in patients on peritoneal dialysis presumably is caused by inadvertent bacterial contamination of the dialysate or tubing during an exchange or by extension of an infection of the exit site or subcutaneous tunnel into the peritoneal cavity. Most cases of peritonitis are caused by *Staphylococcus aureus* or *Staphylococcus epidermidis*, and most of the remainder (≈30%) by gram-negative enteric organisms. Fungal infections are uncommon but generally are refractory to medical therapy and are often considered as an indication for catheter removal. Polymicrobial infection suggests direct contamination from the GI tract and mandates a search for the site of perforation or fistula, although such a source is identified in only a minority of cases. No organism is identified in approximately 10% to 20% of cases of peritoneal dialysis–associated peritonitis.

The diagnosis of peritonitis usually is made by the patient when a cloudy dialysate effluent is noted, corresponding with the appearance of white blood cells (WBCs) in the dialysate. Peritonitis is often, but not invariably, accompanied by nonspecific abdominal pain, malaise, or fever. When a patient has fever or abdominal symptoms, even in the absence of cloudy fluid, it is advisable to consider peritonitis and check the fluid, because early peritonitis may manifest in an atypical manner. In more severe cases, peritonitis is accompanied by nausea, vomiting, severe pain, and hypotension, necessitating hospitalization and consideration of the possibility of acute surgical disease.

In the ED setting, the diagnosis of peritonitis is confirmed by the finding of more than 100 WBCs/mm³ in the peritoneal fluid, with more than 50% neutrophils, or by a positive result on Gram staining. A sample of fluid is obtained for analysis. If a specialized dialysis nurse is available to obtain the fluid, this may be preferable. If not, the fluid is obtained through the use of sterile technique. Fluid is sent for cell count and differential, Gram staining, and culture, with the use of blood culture bottles.

Peritoneal dialysis–associated peritonitis is treated with an initial IP loading dose of antibiotic, followed by a 10- to 14-day course of IP antibiotics self-administered by the patient on an outpatient basis. After the diagnosis has been confirmed, consultation with the patient’s nephrologist or dialysis nurse specialist is indicated to determine antibiotic therapy and a plan for outpatient management and follow-up evaluation or, occasionally, if peritonitis is severe or outpatient management is precluded by psychosocial considerations, for hospitalization. A common treatment regimen is a loading dose of vancomycin, 30 mg/kg IP, followed by further IP doses every 5 to 7 days, plus ceftazidime or cefepime, 1 g IP, or gentamicin, 0.6 mg/kg IP. The last two regimens are given as a loading dose followed by maintenance doses administered IP once daily at the time of an exchange. Heparin, 500 to 1000 units, also may be added to each bag of dialysate for the first few days of treatment to help reduce the formation of fibrin strands that may obstruct the catheter. Patients should be seen by the dialysis nurse in 24 to 48 hours for assessment of the response to therapy and adjustment of antibiotic therapy as necessary after review of the results of culture and sensitivity testing.
Catheter contamination or leaks from the catheter, tubing, or dialysate bag should be managed in the same fashion as for frank peritonitis. The site and cause of leakage are identified, and damaged elements are promptly replaced. Occasionally, with leakage of peritoneal fluid from around the catheter, surgical correction of the underlying problem will be necessary.

Patients who have severe abdominal pain, vomiting, ileus, chills or high fever, or hypotension require hospital admission and management. Likewise, patients with severe underlying illness and those who cannot reliably perform exchanges or administer antibiotics at home also require inpatient management. Dialysis exchanges are continued on the same schedule. The inpatient antibiotic regimen is essentially the same as for outpatients.

Perhaps the most serious potential pitfall in caring for the patient maintained on peritoneal dialysis with abdominal pain or other signs of peritonitis is to overlook other serious intra-abdominal conditions whose presentation may mimic that of peritonitis. Patients on peritoneal dialysis are at increased risk for abdominal wall or inguinal hernia because of chronically increased intra-abdominal pressures; previous abdominal surgery also places them at risk for hernia, as well as for obstruction secondary to adhesions. The manifestations of serious disorders unrelated to dialysis (eg, acute appendicitis, diverticulitis, cholecystitis, acute pancreatitis, ischemic bowel, perforated viscus) also may be attributed to ordinary peritoneal dialysis–associated peritonitis, with the potential to disastrous consequences. The accessibility of the peritoneal fluid for examination may prove to be helpful in documenting the presence of an inflammatory process, but it also has the potential to mislead ED investigation of its cause. A finding of brownish or fecal material in the peritoneal drainage should suggest a ruptured viscus until proven otherwise, and immediate surgical consultation should be sought. Detection of a localized tenderness, palpable mass, or incarcerated hernia on physical examination may be extremely helpful in making the diagnosis. Abdominal radiography may be useful for demonstrating the presence of ileus, but pneumoperitoneum may reflect only the introduction of air during a recent fluid exchange rather than a perforated viscus.

Infection of the catheter exit site or tunnel is another relatively common problem for which the patient on chronic peritoneal dialysis may seek care in the ED. These infections tend to be caused by typical skin flora and manifest with local signs of infection. Although not serious in themselves, exit site infections may lead to infection of the subcutaneous tunnel, which can cause repeated episodes of peritonitis and may ultimately necessitate removal of the catheter. Any visible exudate is cultured and Gram-stained, and therapy with an oral antibiotic such as cephalaxin or dicloxacillin is started, pending the results of culture and sensitivity testing. The patient is instructed to cleanse the site meticulously several times a day using povidone-iodine or peroxide solution.

Tunnel infections can be difficult to detect on physical examination and may be suspected only after the patient has several bouts of peritonitis caused by the same organism. As with other closed space infections, tunnel infections tend to be difficult to eradicate unless the tunnel is partially unroofed and drained.

Patients maintained on peritoneal dialysis also may come to the ED with any of several basically mechanical problems, of which the most common is failure of the dialysate to drain completely at the time of an exchange. Occasionally this problem is caused simply by kinking or inadvertent clamping of the external catheter or tubing. More often, though, it is the result of catheter obstruction by fibrinous debris or kinking or migration of the catheter within the peritoneal cavity, often associated with constipation. Catheter position is best assessed initially by plain radiography of the abdomen. Specific intervention may be guided by a so-called contrast catheterogram. Fibrinolytic agents have been used successfully to open occluded catheters, but surgical intervention for catheter replacement often is required.

Severe metabolic disturbances are much less common among patients on peritoneal dialysis than patients on hemodialysis, because in the former group dialysis is being performed essentially continuously and the blood remains in near-equilibrium with the dialysate. However, significant disturbances do occasionally occur, usually in association with hypercatabolic states, major dietary indiscretions, or significant GI fluid loss. One derangement that occurs occasionally in diabetic patients undergoing peritoneal dialysis is a syndrome of severe hyperglycemia—sometimes even despite continuation of the usual insulin dose—that results from absorption of glucose from the hyperosmolar dialysate, with associated nonspecific symptoms of malaise, weakness, and headache. Although glucose levels may be as high as 1500 mg/dL in these patients, they cannot undergo an osmotic diuresis and remain clinically euvoletic. Correction of hyperglycemia must be undertaken carefully to avoid causing rapid osmolar and volume shifts.

### Key Concepts

- The causes of AKI can be classified as prerenal, postrenal, and intrinsic renal disorders. Abrupt cessation of glomerular filtration typically results in a rise of the serum creatinine level of 1 to 2 mg/dL per day.
- Management of AKI is directed first at potentially lethal complications such as hyperkalemia or volume overload and then at reversal of the underlying cause of renal dysfunction. It is important to avoid any further hemodynamic or toxic insults to the kidneys.
- Patients with acute or chronic kidney disease have a limited ability to handle fluid and solute loads and have altered metabolism of many drugs. Therefore, the patient’s impaired renal function must be considered when fluid is administered or drugs are prescribed.
- The most rapidly lethal complication of acute and chronic kidney disease is hyperkalemia.
- The most common problems with vascular access devices used for hemodialysis are thrombosis, hemorrhage, and infection. Access infection often presents as fever without an obvious source and, in this case, appropriate IV antibiotics should be administered presumptively while awaiting blood culture results.
- Peritoneal dialysis–associated peritonitis typically presents with cloudiness of the peritoneal dialysate effluent. The diagnosis is made by a positive Gram stain or finding of more than 100 WBC/mm³ in the effluent, with at least 50% polys. It is generally treated on an outpatient basis with intraperitoneal antibiotics self-administered by the patient.
- Chest pain in the dialysis patient should be presumed initially to be due to acute coronary syndrome, although other potentially serious causes may also be responsible. Serum troponin levels tend to be elevated in patients with poor renal function, but patients with myocardial infarction show the typical temporal pattern of rise and fall of troponin levels.
- Hypotension in CKD patients is often caused by infection, but may also be the result of rapid fluid removal during dialysis. This often responds readily to fluid administration. Percutaneous tamponade is another cause of hypotension that should be considered for these patients.
- Altered mental status is most commonly due to causes similar to those seen in patients without renal disease, but is sometimes the result of overrapid shifts in intravascular fluid and solutes during dialysis, termed disequilibrium syndrome.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
87.3. What is the most common cause of nontraumatic hematuria?
A. Carcinoma of the kidney or bladder
B. Cystitis
C. Kidney stones
D. Prostatic hyperplasia
E. Transfusion reaction

Answer: C. In descending frequency, the most common causes are kidney stones, lower urinary tract infection (UTI), benign prostatic hypertrophy (BPH), carcinoma of the kidney or bladder, urethritis, and glomerulonephritis.

87.4. A 53-year-old man presents with painless gross hematuria. His only past medical history is an aortic valve replacement for which he takes warfarin. The physical examination is nonfocal. Laboratory evaluation is remarkable for a normal chemistry panel and blood count, too numerous to count (TNTC) red blood cells (RBCs) on urinalysis, and international normalized ratio (INR) of 1.8. What is the next indicated step?
A. Admission and observation
B. Parenteral vitamin K
C. Reassurance
D. Renal imaging
E. Withholding warfarin (Coumadin) for 3 days

Answer: D. When hematuria is associated with anticoagulant use, underlying disease can be identified in a significant proportion of patients.

87.5. A 33-year-old woman presents with mild nonfocal abdominal pain and subjective fever. Her past medical history is significant for hypertension-induced renal failure, for which she is on peritoneal dialysis (PD). The physical examination is remarkable for a temperature of 38°C (100.4°F), blood pressure 190/110 mm Hg, and mild nonfocal abdominal pain. Slightly cloudy peritoneal fluid is aspirated from the PD catheter and sent for analysis. Which of the following statements regarding this patient’s condition is correct?
A. A peritoneal fluid white blood cell (WBC) count >50/mm³ is diagnostic.
B. Intravenous antibiotics should be started empirically.
C. Most cases are due to Staphylococcus.
D. No organism is identified in 50% of cases.
E. Polymicrobial infections suggest sample contamination.

Answer: D. Most PD-associated cases of peritonitis are due to Staphylococcus aureus or Staphylococcus epidermidis. No organism is identified in 20% of cases. A polymicrobial infection warrants GI evaluation for possible perforation or intra-abdominal abscess. A PD fluid count >100 cells/mm³, with a neutrophil count >50% or positive Gram stain, is considered confirmatory. Treatment is typically with intraperitoneal antibiotics given for a 10- to 14-day course.

REFERENCES
Sexually transmitted diseases (STDs) are a diverse group of conditions caused by more than 30 viral, bacterial, and parasitic organisms that are transmitted through sexual contact. Approximately 20 million newly acquired STDs occur in the United States each year, with an estimated $16 billion in associated health care costs. STDs are seen across all demographic, cultural, and socioeconomic strata; and all sexually active persons are at risk for acquiring them. Factors associated with higher risk for STDs reflect the importance of individual sexual practices and risk-taking behaviors (ie, multiple sex partners, substance abuse, commercial sex workers, men who have sex with men, and unsafe sex practices), as well as various demographic and social determinants that influence health status (ie, adolescents and young adults, minorities, and low socioeconomic status).

STDs are among the most common urogenital conditions encountered in the emergency department (ED). The management of patients with STDs is particularly challenging for multiple reasons: (1) the clinical presentation is highly variable; (2) available diagnostic tests have limited sensitivity and results are usually delayed; (3) compliance with treatment, follow-up, and partner notification is often poor; and (4) misdiagnosis and suboptimal treatment can result in serious sequelae. In addition to the morbidity associated with individual STDs, many of these infections also increase the risk of human immunodeficiency virus (HIV) transmission and acquisition in both the infected person and their sexual partners. Thus, STDs have a significant impact on individual and public health.

Patients with STDs frequently present with complaints related to the genitalia but may also present with a variety of nonspecific dermatologic, gastrointestinal, musculoskeletal, and systemic complaints. Because the signs and symptoms of many common STDs are often nonspecific, one must maintain a high level of awareness for these conditions and their associated complications. A thorough history, including sexual history, and focused physical examination facilitate appropriate diagnosis and treatment. The sexual history should include number and gender of sexual partners, types of sexual practices, use of barrier contraception (condoms), and past history of STDs. Obtaining an accurate sexual history may be difficult due to the sensitive nature of the subject, lack of established physician-patient rapport, and other constraints of the ED setting. Evaluation is facilitated by the use of a nonjudgmental approach, maintenance of patient privacy, and assurance of confidentiality.

The differential diagnosis for STDs is extensive, including many other infectious and noninfectious conditions. Most STDs can be broadly categorized as conditions characterized by one of the following manifestations: genital ulcers, genital discharge, epithelial cell infections, and infestation by ectoparasites. Some STDs, such as syphilis, frequently have associated systemic symptoms in addition to their genital manifestations. Other STDs, such as HIV, may have systemic manifestations in the absence of genitourinary signs and symptoms.

STDs frequently coexist. Diagnosis of one STD should prompt consideration of other coexisting infections, which may not be clinically apparent. Screening for other STDs, including HIV, should be considered, because early diagnosis and treatment benefits both the individual patient and the public health. Despite current recommendations from the Centers for Disease Control and Prevention (CDC) for routine HIV screening among patients age 13 to 64 years in all health care settings, systematic HIV testing is not routinely performed in most EDs. When available, rapid HIV testing should be considered. Patients should be counseled regarding the need for HIV testing if it is not performed in the ED.

Empirical antibiotic treatment designed to cover the most likely infecting organisms is recommended for patients with suspected STDs to maximize eradication of disease in the individual patient and reduce the spread of infection to other susceptible persons. Empirical therapy is particularly important when there are concerns about the patient’s ability to obtain appropriate follow-up care. Confirmatory diagnostic studies should still be considered, even when empirical therapy is provided. Microbiologic diagnosis confirms the appropriate choice of empirical therapy, provides guidance for potential changes in treatment, and facilitates reporting of specific STDs to public health authorities.

The diagnosis of an STD provides the physician with a “teachable moment” to educate the patient regarding important factors, including (1) nature of the infection and how it is transmitted; (2) compliance with prescribed therapy and recommended follow-up; (3) importance of preventive measures, including condom use and other safe sex practices; and (4) partner notification and treatment. Patients diagnosed with STDs should be counseled to abstain from sexual intercourse for at least 7 days after the patient and partner(s) complete treatment. Proper counseling helps to ensure the success of initial treatment and reduce the incidence of reinfection. When the diagnosis of an STD is suspected but not confirmed, the patient should be informed of the uncertainty of the diagnosis and the rationale for empirical treatment. The physician should be sensitive to the stress and anxiety that may ensue when discussing the diagnosis of an STD, particularly with a patient who assumes he or she is in a monogamous relationship. A respectful, nonjudgmental, and compassionate manner should be maintained.

The CDC supports the use of expedited partner therapy (EPT) to ensure treatment in sexual partners of selected patients diagnosed with gonorrhea or chlamydia. With EPT, the clinician provides patient-delivered treatment for sexual partners without personally evaluating them. Although EPT may be suitable in some practice settings, its use in the ED is potentially problematic due to lack of knowledge regarding the partner’s medical history, allergies, pregnancy status, and other factors. In addition, some states prohibit the prescribing or dispensing of medications to patients who have not been seen and are unknown to the provider. Updated information regarding the use of EPT and applicable state regulations is available online from the CDC website. All patients diagnosed with an STD in the ED should be advised to notify their sexual partners to seek prompt evaluation and treatment.

An organized mechanism for follow-up of positive diagnostic test results is recommended when these results are not available...

Until after the patient and physician have left the ED. Obtaining accurate contact information at the time of the initial ED visit is important in ensuring timely patient notification. Reporting requirements vary by state, but the following STDs must be reported in all 50 states: gonorrhea, chlamydia, syphilis, chancroid, and HIV. Reporting may be laboratory-based or provider-based, or both. The clinician should be familiar with applicable state reporting requirements and the reporting mechanism used at their hospital.

This chapter reviews the clinical features, diagnosis, and treatment of selected common STDs encountered in the ED setting. Readers are referred to the “Sexually Transmitted Diseases Treatment Guidelines” published by the Centers for Disease Control for additional information regarding the diagnosis and treatment of these conditions, as well as other less common STDs. Updates regarding changes in treatment guidelines are provided by the CDC in the Morbidity and Mortality Weekly Report, available at www.cdc.gov/mmwr.

## DISORDERS CHARACTERIZED BY GENITAL ULCERS

Genital ulcers may be caused by several different STDs, as well as various other infectious and noninfectious conditions. Genital herpes is the most common ulcerating STD seen in the United States, followed by syphilis. Chancroid is an uncommon cause of genital ulcers in the United States, and other STDs that may be manifested by genital ulcers (lymphogranuloma venereum, granuloma inguinale) are rare. Although the history, clinical appearance of the ulcers, and other associated findings provide helpful clues in differentiating the various causes of genital ulcers, these features are not specific enough to provide a definitive diagnosis. Diagnostic studies such as dark field microscopy, serology for syphilis, polymerase chain reaction (PCR), and viral culture should be considered to discriminate between the various etiologies and facilitate a definitive diagnosis, even when empirical therapy is initiated. Diagnostic testing is particularly important in patients that are unresponsive to previous empirical antibiotic therapy. Ulcerating STDs play an important role in facilitating the transmission and acquisition of HIV.

### Herpes

**Principles**

Genital herpes is a lifelong viral infection caused by one of two types of herpes simplex virus (HSV): HSV-1 or HSV-2. Sexual transmission occurs more commonly with HSV-2, with an estimated 50 million people infected in the United States alone. Many cases are undiagnosed. HSV is often transmitted by persons who are unaware that they are infected, or who are asymptomatic at the time of transmission. HSV transmission occurs through viral contact with a break in the skin or intact mucous membranes. The average incubation period is 4 days but may range from 2 to 12 days. The virus ascends via sensory nerves to the dorsal root ganglia, where it becomes latent but may reactivate periodically. Herpes, like other ulcerating STDs, facilitates the transmission and acquisition of HIV. Herpes infection in pregnant women may result in transmission to the infant at the time of delivery, with devastating associated neonatal morbidity and mortality.

#### Clinical Features

Typical herpetic lesions begin as a cluster of small erythematous painful vesicles, which quickly ulcerate (Fig. 88.1). Lesions may occur anywhere the organism is inoculated, but they are typically seen on the skin of the external genitalia, perineum, and buttocks and on the mucous membranes of the vagina, rectum, and oropharynx. Primary infection occurs when a patient is infected with HSV-1 or HSV-2 with no preexisting antibodies to either type. The primary infection is usually more painful and symptomatic, with associated tender regional lymphadenopathy, fever, malaise, headache, and other systemic symptoms. Dysuria is common due to the proximity of the lesions to the urethra. The symptoms of untreated primary infection typically last from 2 to 4 weeks before resolving spontaneously.

Nonprimary infection occurs when a patient is infected with HSV-1 or HSV-2 and has preexisting antibodies to other viral type (i.e., a patient with preexisting antibodies to HSV-1 due to orolabial herpes becomes infected with HSV-2 causing genital herpes). Patients with a nonprimary infection typically have fewer skin lesions and less systemic symptoms than those with primary infections. Recurrent episodes tend to be less symptomatic and shorter in duration, with lesions occurring in the same distribution due to reactivation of latent infection in the affected nerve roots. Recurrences are more frequent with infection caused by HSV-2 than with HSV-1. Recurrent outbreaks are often heralded by prodromal symptoms of itching, burning, and paresthesias prior to the development of skin or mucous membrane lesions. Reactivation of latent HSV may occur in response to a variety of stressors, including acute illness or injury, immunosuppression, psychological stress, and menses. Recurrences typically become less frequent and less severe over time. Extragential complications of HSV infection include meningoencephalitis, transverse myelitis, hepatitis, pneumonitis, transverse myelitis, and disseminated

infection. Asymptomatic viral shedding and transmission occurs even in the absence of visible lesions on the skin or mucous membranes.

### Diagnostic Testing

The diagnosis of genital herpes is frequently made based upon clinical findings. Although the presence of typical skin or mucous membrane lesions is suggestive of herpes, the clinical diagnosis is both insensitive and nonspecific. A history of similar lesions in the same anatomic distribution supports the clinical diagnosis. PCR is the diagnostic test of choice, with the highest sensitivity and specificity in the presence of active lesions. Viral culture is also specific but less sensitive than PCR. Dark-field microscopy and serologic testing for syphilis should be considered to help differentiate cases of syphilis. The utility of these diagnostic studies is limited in the ED because test results are delayed, but results may be helpful at the time of follow-up. Direct fluorescent antibody (DFA) and serology for HSV are available, but less commonly used in the ED setting. Cytologic testing (Tzanck preparation) is nonspecific and insensitive and should not be relied upon to make the diagnosis of HSV.

### Management

Genital herpes is treated with the antiviral medications acyclovir, famciclovir, or valacyclovir. Antiviral therapy is not curative but has been shown to decrease the duration and severity of symptoms and the development of complicated HSV infection, particularly when started early during the primary infection. Prompt initiation of antiviral treatment is key to obtaining optimal clinical benefit. Although most studies have evaluated drug initiation within 72 hours of symptom onset, antiviral therapy may still be offered after this time frame in the presence of ongoing symptoms and the development of new lesions. Multiple regimens are available for treatment of primary and recurrent episodes of genital herpes with oral antiviral medications (Table 88.2). Oral antiviral therapy is generally well tolerated with few side effects. Suppressive therapy with daily antiviral use has been shown to decrease the frequency of recurrences while the medication is being taken, but it does not affect the frequency or severity of recurrences after the drug is discontinued. Topical antiviral therapy provides minimal clinical benefit and is not recommended.

### Disposition

Most patients with genital herpes are managed as outpatients. Hospitalization for parenteral therapy with acyclovir is indicated for systemic complications of HSV infection, including meningencephalitis, hepatitis, pneumonitis, and disseminated infection. Patients with genital herpes should be counseled that transmission may occur even in the absence of clinical symptoms. Condom use has been shown to reduce but not eliminate the incidence of HSV transmission. Discordant couples (ie, those in which one partner is HIV+) should be advised to avoid sexual contact during active outbreaks, which is when viral transmission is highest. Condoms should be used during asymptomatic periods. Patients with genital herpes should also be counseled regarding the increased risk of acquisition and transmission of HIV in the presence of genital ulcers.

### Syphilis

#### Principles

Humans are the only known host for *Treponema pallidum*, the spirochete that causes syphilis. The incidence of syphilis has
detracted significantly since penicillin became widely available in 1945, but outbreaks still occur intermittently. After a progressive decline in the incidence of syphilis from 1990 to 2000, there has been an increase in recent years. More than 17,000 cases of primary and secondary syphilis were reported to the CDC in 2013. The rates of primary and secondary syphilis are higher among those between 20 to 29 years old, minority groups, and men who have sex with men. It is more common in the southeastern United States compared to other regions of the country.

Clinical Features

Syphilis has been called “the great imitator,” because its clinical manifestations are protean. Syphilis is divided into primary, secondary, latent, and tertiary stages based upon clinical and serologic findings. The primary and secondary stages of syphilis are most commonly seen in the ED setting. Transmission occurs when the spirochetes gain access through disrupted epithelium of the skin or mucous membranes. The average incubation period is approximately 21 days but may range from 3 to 90 days.

**Primary syphilis** is initially manifested by the development of a painless papule at the site of inoculation. The lesion ulcerates, forming the chancre of primary syphilis (Fig. 88.2). The chancre is classically described as a relatively painless clean-based ulcer with well demarcated indurated edges, measuring approximately 1 to 2 cm in size. Nontender regional lymphadenopathy may be seen. Although the chancre often occurs in the genital or perianal area, it may occur at any site of inoculation, including the oropharynx, breasts, hands, and other sites. The chancre will heal spontaneously over the course of 3 to 6 weeks. Because the chancre is relatively painless, it may go unnoticed by the patient.

**Secondary syphilis** will develop in approximately 25% of patients with primary syphilis over a period of several weeks to months. Manifestations of secondary syphilis include rash, generalized lymphadenopathy, mucous membrane lesions, and systemic symptoms. The rash is diffuse, involving the face, trunk, and extremities, including the palms and soles. The appearance of the rash is highly variable. Lesions may be macular, papular, scaly, or pustular in appearance (Fig. 88.3). Mucous patches are multiple shallow erosions of the oropharyngeal mucosa that are usually accompanied by other dermatologic and systemic manifestations of secondary syphilis. Condyloma lata, which resemble genital warts, are broad-based papular lesions that occur on the genitalia and perineum and typically have a moist surface appearance (Fig. 88.4). Lymphadenopathy is typically diffuse, rubbery, and nontender. Epitrochlear adenopathy is particularly suggestive of secondary syphilis. A nonspecific “moth-eaten” alopecia may be seen. Systemic manifestations include low-grade fever, anorexia, headache, malaise, myalgias, and weight loss. Symptoms of secondary syphilis will resolve without treatment, with subsequent progression to latent syphilis.

**Latent syphilis** is present when there is serologic evidence of syphilis infection in the absence of any clinical signs or symptoms. Latent infection acquired within the past 12 months is defined as early latent syphilis, whereas late latent syphilis includes cases of latent infection of greater than 12 months or unknown duration. Patients with early latent syphilis are considered to be infectious. Those with late latent syphilis are generally not infectious, with an important exception—pregnant women with late latent syphilis can transmit the infection to the fetus. Latent syphilis can persist indefinitely before progressing to tertiary syphilis. **Tertiary syphilis**, which includes cardiovascular manifestations and gummatous disease, is uncommon in the United States. Aortitis, aortic aneurysm, and gummatous lesions of the skin, bones, and other organs may be seen. In patients with untreated syphilis, the estimated risk of eventual progression to tertiary
syphilis ranges from 25% to 40%. Neurosyphilis refers to infection involving the central nervous system (CNS) and may be seen in any stage of syphilis. Manifestations of neurosyphilis include altered mental status, meningitis, cranial nerve abnormalities, stroke, peripheral neuropathy, and auditory and ophthalmic abnormalities. Congenital syphilis, which is transmitted perinatally to the fetus, is relatively uncommon in recent years in the United States but has significant associated morbidity in infected children.

Diagnostic Testing

T. pallidum is fastidious and cannot be cultured in the laboratory. The diagnosis of syphilis can be confirmed with darkfield microscopy or by serologic testing. Visualization of the spirochete on darkfield examination of specimens obtained from a chancre or from the moist lesions of secondary syphilis provides an immediate diagnosis. Dark-field microscopy is particularly useful in primary syphilis when false negative serology is common. The sensitivity and specificity of dark field microscopy vary depending upon the experience of the microscopist and the use of proper specimen collection techniques. The utility of darkfield microscopy is limited by the need for specialized laboratory equipment and appropriately trained personnel, which are lacking at many hospitals. Serologic tests for syphilis include nonspecific nontreponemal tests and specific treponemal tests. Both types of serologic testing are necessary for the proper diagnosis of syphilis. Nontreponemal tests include the Venereal Disease Research Laboratory (VDRL) and the rapid plasma reagin (RPR). The VDRL and RPR provide quantitative measurements of nonspecific antibodies that are produced in response to T. pallidum infection. The titers correlate with disease activity, typically rising with active syphilis infection and declining after successful treatment. The sensitivity of nontreponemal tests is approximately 70% to 80% in primary syphilis but rises to nearly 100% in secondary syphilis. False positive nontreponemal tests may be seen in a variety of conditions, including pregnancy, endocarditis, autoimmune disease, and other acute or chronic illnesses. A positive nontreponemal test should always be confirmed with a specific treponemal test. Specific treponemal tests include the fluorescent treponemal antibody absorption (FTA-ABS) and the microhemagglutination test for antibodies to T. pallidum (MHA-TP). These treponemal tests provide qualitative measurements of specific antitreponemal antibodies. Although these treponemal tests are highly specific for syphilis, they may remain positive for life even after successful treatment and cure. A non treponemal test is used for screening purposes and serves as a better marker for acute infection, with the specific treponemal test used to confirm the diagnosis.

Disposition

Most cases of syphilis are treated on an outpatient basis. Hospitalization is recommended for patients with penicillin allergy who require desensitization prior to penicillin therapy, including pregnant women with syphilis and patients with neurosyphilis or congenital syphilis.

Chancroid

Principles

Chancroid is an ulcerating STD caused by the gram-negative organism Haemophilus ducreyi. Chancroid is common in parts of the developing world but is rare in the United States, with only 10 cases reported in 2013. Like other ulcerating STDs, chancroid is a cofactor for the transmission and acquisition of HIV.

Clinical Features

After an incubation period of less than 1 week, a tender erythematous papule develops at the site of inoculation. The initial lesion rapidly ulcerates, and multiple painful ulcers subsequently develop (Fig. 88.5). The ulcers typically have an irregular, inflamed, and “dirty” appearance compared to the well circumscribed clean-based chancre of syphilis, and the smaller punched-out appearance of herpetic ulcers. Painful inguinal lymphadenopathy is common and may progress to bubo formation. A bubo is a large, painful, fluctuant unilateral inguinal lymph node, which may spontaneously rupture and drain purulent material.

Management

Penicillin is the cornerstone of treatment for syphilis, with T. pallidum remaining highly sensitive to penicillin. The dosage and preparation of penicillin and the length of treatment vary depending upon the stage of the disease and the associated clinical manifestations (see Table 88.2). A single dose of long-acting benzathine penicillin G (2.4 million units intramuscularly) is curative in the majority of cases of primary, secondary, and early latent syphilis. Patients with significant penicillin allergy can be treated with doxycycline or tetracycline for 2 weeks if no contraindication to these drugs exists. Ceftriaxone has antitreponemal activity, but the optimal dosage and duration of therapy have not been established. Azithromycin has some efficacy but is not recommended as a first line therapy due to documented resistance and treatment failures. Penicillin remains the drug of choice for patients with neurosyphilis, congenital syphilis, and syphilis during pregnancy, even in the presence of penicillin allergy, due to the known efficacy of penicillin and the absence of proven alternative therapies. Patients with these conditions should be admitted for desensitization and treatment with penicillin.

The Jarisch-Herxheimer reaction is an acute worsening of symptoms that may develop after antibiotic therapy is initiated for syphilis. The patient typically reports worsening malaise, myalgias, and fever within 24 hours of antibiotic treatment. The condition has traditionally been thought to be caused by the sudden lysis of spirochetes, but the mechanism is poorly understood. Treatment is supportive, including rest, hydration, and antipyretics. The symptoms resolve spontaneously. Anticipatory guidance regarding the appropriate management of this common self-limited reaction may prevent a return visit to the ED.

Fig. 88.5. Multiple vulvar ulcers due to chancroid. (From Morse S, Ballard RC, Holmes KK, et al, editors: Atlas of sexually transmitted diseases and AIDS, ed 4, London, 2010, Saunders/Elsevier, Fig. 8.14, p 219.)
PART III

Diagnosis and Treatment of Specific Genitourinary and Gynecologic Disorders

Gonorrhea

Principles

Gonorrhea is the second most commonly reported STD in the United States, with more than 300,000 cases reported to the CDC annually. Humans are the only reservoir for the causative organism Neisseria gonorrhoeae, a gram-negative intracellular diplococcus. The prevalence of gonorrhea varies widely, with higher rates of gonorrhea seen among adolescents and young adults, minorities, people with low socioeconomic status, those with a history of substance abuse, and those who engage in high-risk sexual behaviors.

Clinical Features

The signs and symptoms of gonorrhea vary depending on the sex of the patient, the site of inoculation, and the local or systemic spread of the infection. The incubation period for gonorrhea typically ranges from 3 to 7 days. Most men with gonococcal urethritis become symptomatic within 1 to 2 weeks, prompting them to seek curative treatment. Patients complain of urethral discharge and dysuria. The discharge is usually copious and purulent, although the clinical appearance alone cannot differentiate gonococcal urethritis from NGU (Fig. 88.6). Women with gonococcal cervicitis are often asymptomatic until ascending infection develops. Because many women remain asymptomatic for prolonged periods, a larger reservoir of untreated women exists. When present, symptoms of gonococcal cervicitis may include abnormal vaginal discharge, dyspareunia, and intermenstrual bleeding. Women with gonococcal cervicitis may also complain of dysuria due to associated urethritis.

Gonococcal proctitis may occur in men and women who engage in receptive anal intercourse and in women who are inoculated by infected vaginal secretions. Patients with gonococcal proctitis are often asymptomatic but may complain of rectal pain, tenesmus, rectal discharge, or bleeding. Anoscopy may reveal abnormal discharge and inflamed friable rectal mucosa.

Management

Patients with chancroid are treated as outpatients. Single-dose therapy with azithromycin or ceftriaxone is recommended for suspected chancroid (see Table 88.2). Alternative treatment regimens include oral ciprofloxacin or erythromycin.

Disorders Characterized by Genital Discharge

Some STDs, including gonorrhea, chlamydia, trichomoniasis, and pelvic inflammatory disease (PID), are frequently characterized by the presence of genital discharge in absence of genital ulcers and lymphadenopathy. The differential diagnosis of genital discharge is broad, including infections that are not sexually transmitted and noninfectious conditions (see Table 88.1). For example, bacterial vaginosis and candidiasis are common conditions that are not considered to be sexually transmitted but are frequently found during the evaluation of a woman with vaginal discharge. Urethritis, cervicitis, and vaginitis caused by various organisms can present with associated genital discharge.

Infectious causes of urethritis are generally divided into two categories: gonococcal urethritis and nongonococcal urethritis (NGU). Urethritis occurs in men and women and may be asymptomatic, particularly in persons with NGU. When present, symptoms include dysuria, urethral pruritus, and urethral discharge. The absence of visible discharge does not exclude the diagnosis. A clinical diagnosis of urethritis can be made on the basis of any of the following findings in the setting of compatible symptoms: (1) mucoid, mucopurulent or purulent urethral discharge, (2) Gram stain of urethral discharge containing two or more white blood cells (WBCs) per oil immersion field, (3) first-void urine sediment containing 10 or more WBCs per high-power field, and (4) positive leukocyte esterase test on first-void urine. Diagnosis and management of specific causes of urethritis are discussed later.

Cervicitis is characterized by the presence of purulent or mucopurulent discharge from the endocervix and the presence of cervical friability. Many women with cervicitis are asymptomatic. The discharge may be visible in the endocervical canal or noted on an endocervical swab specimen. Cervical friability is demonstrated when endocervical bleeding is easily induced with gentle passage of a swab through the cervical os. Gonorrhea and chlamydia are common causes, but trichomonas and HSV may also cause cervicitis. Frequently, no organism is isolated despite the presence of clinical findings consistent with cervicitis. Women with cervicitis may complain of abnormal vaginal discharge, dyspareunia, and postcoital vaginal bleeding. Pelvic examination may demonstrate endocervical discharge and friability as described earlier. These findings are insensitive, and the absence of these findings on history and examination do not exclude the diagnosis of cervicitis. Specific causes of cervicitis and their management are discussed later.
Gonococcal pharyngitis is usually acquired from oral sexual exposure. Patients with pharyngitis are usually asymptomatic but may complain of sore throat. Tonsillar erythema and cervical lymphadenopathy may be present.

Gonococcal conjunctivitis was historically seen most often in infants born to infected mothers. Because infants are now routinely prophylaxed at birth, gonococcal conjunctivitis is now more common in adults who self-inoculate by rubbing the eye with contaminated fingers. Severe conjunctival infection with copious purulent discharge is typically seen. The infection can progress rapidly to corneal ulceration, perforation, and blindness if untreated.

Disseminated gonococcal infection (DGI) results from hematogenous spread of *N. gonorrhoeae*. DGI may occur in the absence of any signs or symptoms of the initial local infection. Characteristic clinical findings include rash, polyarthralgias, tenosynovitis, and septic arthritis. The rash usually consists of petechial or pustular lesions in an acral distribution on the distal extremities. The rash is sparse, with 2 to 10 skin lesions being typical and more than 40 lesions uncommon. Septic arthritis presents as a swollen, red, warm, and painful joint. One or more joints may be involved. The knees, wrists, and ankles are the most common sites. Rarer complications of DGI include hepatitis, meningitis, and myocarditis.

**Diagnostic Testing**

In symptomatic men, a Gram stain of urethral discharge that reveals gram-negative intracellular diplococci has a sensitivity and specificity approaching 100% for the diagnosis of gonorrhea. Gram stain results are available rapidly. A positive Gram stain does not exclude coinfection with chlamydia or other organisms. Culture and nucleic acid amplification tests (NAATs) are both useful to confirm the diagnosis. NAATs are widely available and have replaced culture as the diagnostic gold standard. The sensitivity of NAATs for the detection of *N. gonorrhoeae* is higher than that of culture. A wider variety of specimens can be used for NAATs, including first-void urine and swabs from the urethra, cervix, and vagina. Suitable specimens can be obtained by the examining clinician or provided by the patient. Although NAATs is not yet FDA-approved for use with specimens obtained from the oropharynx, rectum, or conjunctiva, some laboratories have established performance specifications and met Clinical Laboratory Improvement Amendment (CLIA) guidelines for use of NAATs with oropharyngeal and rectal specimens. Culture with selective Thayer Martin media is still useful in selected patients and has the advantage of allowing antimicrobial susceptibility testing. Isolation of *N. gonorrhoeae* from the blood, synovial fluid, or skin lesions establishes a definitive diagnosis of DGI, but sensitivity of these cultures is poor. The organism may be more readily identified from other sites (urethra, cervix, rectum, or pharynx) even in the absence of localized symptoms at these sites. When accompanied by the appropriate clinical presentation, identification of gonorrhea by NAATs or culture from any site is sufficient for a presumptive diagnosis of DGI.

**Treatment**

Recommended treatment options for gonorrhea have changed in recent years due to the increasing antimicrobial resistance of *N. gonorrhoeae*. Ceftriaxone remains the drug of choice for the treatment of gonorrhea. Single-dose therapy with an intramuscular injection of ceftriaxone 250 mg is recommended for most cases of gonococcal urethritis, cervicitis, proctitis, and pharyngitis (see Table 88.2). Concomitant therapy with a single dose of azithromycin 1 g per os (by mouth) (PO) is recommended to provide synergistic coverage with ceftriaxone against *N. gonorrhoeae* and coverage of possible coexisting chlamydia infection. Directly observed therapy with both ceftriaxone and azithromycin can be administered in the ED to ensure compliance. The use of oral cephalosporins or fluoroquinolones is no longer recommended for the treatment of gonorrhea due to increasing antimicrobial resistance.10,11 DGI and gonococcal arthritis are treated with parenteral ceftriaxone 1 g daily. Several parenteral antibiotic regimens are available for treatment of severe or complicated PID (discussed later in this chapter).

**Disposition**

Uncomplicated gonococcal infections are treated on an outpatient basis. Hospitalization may be warranted for more severe cases of upper tract infection, such as PID or epididymo-orchitis. Admission and treatment with parenteral ceftriaxone is recommended for DGI, septic arthritis, and conjunctivitis.

**Chlamydia**

**Principles**

Chlamydia is the most commonly reported STD in the United States, with more than 1.4 million cases reported to the CDC in 2013. *Chlamydia trachomatis*, an obligate intracellular organism, is the causative pathogen. Approximately 50% of men and 70% of women who are infected with chlamydia are asymptomatic. Adolescents and young adults 15 to 24 years old have the highest rate of chlamydia infection. The reported rate of chlamydia is twice as high among women compared to men, reflecting the higher number of women screened for this infection.

**Clinical Features**

Chlamydia infection is a common cause of NGU. When present, the urethral discharge associated with chlamydia is typically scant, mucoid, and less purulent than the discharge seen with gonorrhea. Dysuria is less pronounced and presentation is often delayed. Chlamydia cervicitis may present with mucopurulent cervical discharge or postcoital bleeding but is often asymptomatic. When untreated, chlamydia can progress to upper tract infection, including epididymitis and orchitis in men and PID in women. Patients with epididymitis and orchitis complain of unilateral scrotal pain and swelling, and they may also report symptoms of urethritis. Swelling and tenderness of the epididymis and testicle are usually present. Epididymitis is more common with chlamydia infection alone or combined gonorrhea and chlamydia infections, rather than with gonorrhea alone. Chlamydia frequently contributes to the development of PID, which may be indolent or clinically silent, but results in significant chronic sequelae.

**Diagnostic Testing**

Differential diagnosis of chlamydia and gonococcal infection is based solely upon history and physical examination is unreliable, and these infections frequently coexist. NAATs are the diagnostic test of choice, with sensitivity greater than 90% and specificity of 99% for the diagnosis of chlamydia. NAATs assays are approved for use with specimens obtained from the urethra, cervix, vagina, or first-void urine specimens. Some laboratories meet CLIA guidelines to perform NAATs on specimens from the oropharynx and rectum.

**Management**

Recommended treatment regimens for chlamydia urethritis or cervicitis include single-dose azithromycin 1 g PO or a 7-day

*Alternative treatment regimens for selected patients (including pregnancy, drug allergies) can be found at [www.cdc.gov/std/treatment](http://www.cdc.gov/std/treatment). IM, Intramuscular; PO, per os (by mouth).

A course of doxycycline 100 mg PO bid (Table 88.3). Both regimens are equally efficacious when taken as directed, but single-dose azithromycin is preferable if there is concern for possible noncompliance with doxycycline. Azithromycin is the drug of choice in pregnancy. Alternative regimens for the treatment of lower tract chlamydia infection include a 7-day course of erythromycin, levofloxacin, or ofloxacin. Suspected upper genitourinary tract infection with chlamydia (ie, epididymitis, PID) requires a longer course of antibiotic therapy ranging from 10 to 14 days (Table 88.4).

Empirical treatment for both gonorrhea and chlamydia is recommended when confirmatory test results are unavailable, because history and physical examination cannot reliably differentiate these conditions and coinfections often occur. Single-dose ceftriaxone 250 mg IM plus single-dose azithromycin 1 g PO treats uncomplicated gonorrhea in addition to lower tract chlamydia infection.

**Disposition**

Most chlamydia infections are treated on an outpatient basis. Patients with severe upper tract infection and associated complications (tubo-ovarian abscess, severe PID) may require hospitalization for parenteral antibiotics, pain control, antiemetics, hydration, and other measures.

**Nongonococcal Urethritis**

NGU is most often caused by *Chlamydia trachomatis*, but may also be caused by *Trichomonas vaginalis*, *Mycoplasma genitalium*, other *Mycoplasma* species, *Ureaplasma* species, and other organisms. Patients with NGU are often asymptomatic. Symptoms, when present, are usually less prominent than those seen with gonococcal urethritis. Clinical features are not sufficiently specific to distinguish between gonococcal urethritis and NGU, and coinfection is common. NAATs have high sensitivity and specificity for chlamydia and gonorrhea. Wet mount microscopy can identify cases of trichomoniasis. Diagnostic testing is not routinely performed for other causes of NGU. Fortunately, most causative organisms respond to single-dose therapy with azithromycin 1 g PO. Azithromycin is more effective than doxycycline for *M. genitalium*. Additional empirical treatment with single-dose ceftriaxone 250 mg IM is recommended when gonorrhea has not been ruled out with negative NAATs. Single-dose metronidazole 2 g PO is recommended for cases of trichomoniasis.

IM, Intramuscular; IV, intravenous; PO, per os (by mouth).

**Trichomoniasis**

**Principles**

*Trichomonas vaginalis* is the flagellated protozoan organism responsible for trichomoniasis, the most common curable STD worldwide. Women are typically more symptomatic than men, but asymptomatic infection occurs in both sexes. Trichomoniasis usually causes mild disease, but significant morbidity can occur. Trichomoniasis has been associated with PID, preterm birth among pregnant women, prostatitis, epididymitis, and increased susceptibility to HIV acquisition.

**Clinical Features**

Trichomoniasis causes vaginitis in women. Common symptoms include vaginal discharge, pruritus, dysuria, urinary frequency, dyspareunia, and postcoital bleeding. The discharge is classically described as malodorous, frothy, and greenish yellow in color (Fig. 88.7). Pelvic examination may reveal erythema of the vaginal mucosa and vulva, in addition to the discharge. Punctate hemorrhages of the cervix (“strawberry cervix”) are seen in up to 10% of cases. Trichomoniasis is often asymptomatic in men but may cause urethritis with associated dysuria and urethral discharge.
Diagnostic Testing

The diagnosis of trichomoniasis is usually confirmed with microscopic examination of a saline wet mount slide, which reveals motile flagellated trichomonads and leukocytes (Fig. 88.8). The sensitivity of the wet mount slide is approximately 50% to 65%. Trichomonas may be seen incidentally on microscopic analysis of the urine sediment. NAATs are superior to microscopic examination, with reported sensitivity and specificity greater than 95% for some assays. A point-of-care antigen detection test for trichomoniasis is now available. Culture is also confirmatory, but seldom used in the ED.

Management

Treatment of trichomoniasis is indicated in both symptomatic and asymptomatic men and nonpregnant women. Single-dose metronidazole 2 g PO or single-dose tinidazole 2 g PO are both highly effective, with reported cure rates ranging from 90% to 95% (see Table 88.3). Alternatively, metronidazole 500 mg twice daily for 7 days can be used. Metronidazole is the recommended treatment for symptomatic trichomoniasis during pregnancy. A meta-analysis failed to reveal any relationship between metronidazole exposure during the first trimester of pregnancy and the occurrence of birth defects. Current CDC guidelines advise that single-dose therapy with metronidazole may be used during any stage of pregnancy. The treatment of asymptomatic pregnant women with trichomoniasis is controversial, because there is conflicting data regarding the possible increased incidence of preterm labor in pregnant women treated with metronidazole.

Disposition

Trichomoniasis is treated on an outpatient basis. Patients should be counseled to avoid alcohol use for at least 24 hours after completion of metronidazole therapy and 72 hours after completion of tinidazole therapy, due to the occurrence of a disulfiram-like reaction following alcohol use.

Pelvic Inflammatory Disease

Principles

PID is an ascending infection that begins at the level of the endocervix but progresses to the upper reproductive tract, causing endometritis, salpingitis, and peritonitis. N. gonorrhoeae and Chlamydia trachomatis have traditionally been implicated in the development of PID, but many women diagnosed with PID do not test positive for either of these organisms. Negative testing for gonorrhea and chlamydia from endocervical specimens does not reliably exclude them as a cause for upper tract infection. Polymicrobial involvement is common, with anaerobes, enteric organisms, vaginal flora, and other STDs often implicated in PID. An estimated 10% to 20% of women with gonorrhea or chlamydia may develop PID if they do not receive proper treatment. Among women with PID, 18% experience chronic pelvic pain, 9% develop ectopic pregnancy, and 8% develop infertility.

Clinical Features

PID causes a spectrum of illness ranging from asymptomatic infection to severe illness with associated peritonitis and systemic toxicity. Lower abdominal pain is the most common presenting complaint. Other symptoms include dyspareunia, abnormal vaginal discharge or bleeding, dysuria, and fever. Nausea, vomiting, diarrhea, and anorexia may be present, mimicking gastrointestinal conditions. Physical findings may include lower abdominal tenderness, cervical friability, mucopurulent discharge, cervical motion tenderness, and adnexal tenderness. Vital sign abnormalities, such as fever and tachycardia, may be seen.

Diagnostic Testing

PID is a clinical diagnosis. No single historical, physical, or laboratory finding or combination of findings is sufficiently sensitive or specific to make a definitive diagnosis of PID. Because PID causes significant morbidity, the CDC recommends a low threshold for the diagnosis and empirical treatment of PID. The diagnosis of PID should be considered and presumptive treatment initiated in any sexually active woman at risk for STDs who presents with lower abdominal pain or pelvic pain if no alternative diagnosis is identified and if one or more of the following findings are present on pelvic examination: (1) cervical motion tenderness, or (2) uterine tenderness, or (3) adnexal tenderness. These criteria have high sensitivity but low specificity for the diagnosis of PID. Because the use of these criteria will result in the over-diagnosis of PID, one should consider other possible diagnoses. The use of the additional criteria improves the specificity of the diagnosis of PID but decreases the diagnostic sensitivity (Table 88.5).

NAATs for gonorrhea and chlamydia are recommended. A pregnancy test should always be obtained, because ectopic...
pregnancy and other pregnancy-related conditions may mimic PID. Computed tomography (CT) and pelvic ultrasonography may reveal findings supporting the diagnosis of PID, including evidence of swelling and inflammation within the endometrial cavity and fallopian tubes. Imaging studies are also helpful in ruling out other diagnoses, such as appendicitis, and for identifying complications of PID, such as tubo-ovarian abscess. Laparoscopy can confirm the diagnosis but is of limited utility due to its invasive nature, limited availability, and expense. In addition, laparoscopy may not identify mild cases of PID.

Management

Treatment should be initiated as soon as possible after the diagnosis is made and should not await the results of microbiologic testing or other delayed diagnostic studies. Delays in the initiation of antibiotic therapy contribute to the development of complications of PID. Multiple inpatient and outpatient antibiotic regimens are available for the treatment of PID (see Table 88.4). The total duration of antibiotic therapy is 14 days. The addition of anaerobic coverage with metronidazole should be considered. The clinician must weigh the potential benefit of providing broader spectrum antibiotic coverage against the potential risks of antibiotic side effects, greater expense, and patient noncompliance with a more complicated treatment regimen. Supportive care measures include analgesics, antipyretics, and hydration. Sexual intercourse should be deferred until symptoms have resolved and antibiotic therapy has been completed by the patient and her partner.

Disposition

Most women with PID are treated as outpatients. Current recommendations no longer mandate hospitalization for adolescents or for HIV-positive patients with PID.7 Follow-up within 72 hours is recommended to ensure appropriate response to initial treatment. Women who meet any of the following criteria should be considered for inpatient treatment of PID:

- Surgical emergencies cannot be excluded (ie, appendicitis)
- Pregnancy
- Tubo-ovarian abscess
- Severe illness, nausea and vomiting, or high fever
- Inability to follow or tolerate outpatient oral regimens
- Failure to respond to oral antibiotic therapy

In addition to chronic pelvic pain, ectopic pregnancy, and infertility, other complications of PID are common. Tubo-ovarian abscess or pyosalpinx may be identified on pelvic ultrasound or CT. Perihepatitis, known as Fitz-Hugh-Curtis syndrome, is occasionally seen and may result in associated right upper quadrant abdominal pain.

Bacterial Vaginosis

Principles

Bacterial vaginosis is the most common cause of abnormal vaginal discharge in the United States. Although bacterial vaginosis is not considered to be an STD, it is often encountered during the evaluation of patients with an abnormal vaginal discharge. Bacterial vaginosis is due to an alteration in the vaginal flora with replacement of normal Lactobacillus species by a polymicrobial group of organisms, including Gardnerella vaginalis, anaerobes, and others.

Clinical Features and Diagnostic Testing

Many women with bacterial vaginosis are asymptomatic. Symptomatic women complain of a malodorous thin whitish vaginal discharge. A fishy odor is often reported and can be accentuated with the addition of 10% potassium hydroxide (KOH) solution to a wet mount slide at the time of pelvic examination (the “whiff test”). The pH of vaginal fluid is greater than 4.5. Microscopic examination of the wet mount slide reveals clue cells, which are vaginal epithelial cells with indistinct borders due to a coating of bacteria. Bacterial vaginosis is associated with an increased risk of PID and complications of pregnancy (premature rupture of membranes and preterm delivery). Bacterial vaginosis may also be a cofactor in the acquisition and transmission of other STDs, including HIV.

Management

Treatment is recommended for all symptomatic women with bacterial vaginosis, regardless of pregnancy status. The established benefit of therapy is the relief of vaginal symptoms. There is conflicting data regarding the efficacy of treatment in reducing the incidence of associated illnesses in pregnant and nonpregnant women. Treatment of bacterial vaginosis in asymptomatic women is not recommended. Treatment of male sexual partners is of no benefit. Recommended treatment regimens for bacterial vaginosis include: (1) metronidazole 500 mg PO twice a day for 7 days, (2) metronidazole gel 0.75% 5 g intravaginally once a day for 5 days, and (3) clindamycin cream 2% 5 g intravaginally at bedtime for 7 days. Symptomatic pregnant women can be treated with the same oral or topical regimens recommended for nonpregnant women. The use of intravaginal Lactobacillus preparations and other probiotics are of no proven benefit in the restoration of normal vaginal flora or in the treatment of bacterial vaginosis.

Vulvovaginal Candidiasis

Principles

Vulvovaginal candidiasis is usually caused by the yeast species Candida albicans. An estimated 75% of women will have at least one episode of candidiasis during their lifetime, and recurrent episodes are common. Like bacterial vaginosis, candidiasis is not considered to be an STD but is frequently encountered in the evaluation of patients with abnormal vaginal discharge.

Clinical Features and Diagnostic Testing

Common nonspecific symptoms include pruritus, abnormal discharge, dyspareunia, and external dysuria. Pelvic examination

*In a sexually active woman at risk for sexually transmitted diseases (STDs) who presents with abdominal pain and no alternative diagnosis is identified, a presumptive diagnosis of pelvic inflammatory disease (PID) may be based on the criteria listed in this table.

*Additional criteria increase specificity but decrease sensitivity for the diagnosis of PID.*
may reveal the vulvar erythema and edema with satellite lesions, erythema of the vaginal mucosa, and a thick curdy whitish vaginal discharge. Microscopic examination of a wet mount slide may reveal the presence of budding yeast or pseudohyphae. Diagnosis is facilitated with the use of 10% KOH, which disrupts other cellular structures and facilitates visualization of fungal elements. Fungal culture is the diagnostic gold standard but is rarely performed.

Management

Multiple topical antifungal azole drugs are recommended for the treatment of vulvovaginal candidiasis, including clotrimazole, miconazole, butoconazole, terconazole, and tioconazole. Several topical agents are available over-the-counter. Fluconazole is the only oral antifungal agent approved by the FDA for treatment of candidiasis. A single dose of fluconazole 150 mg PO is highly effective in nonpregnant women but is contraindicated during pregnancy. A 7-day course of topical azoles is recommended during pregnancy. Single-dose and short-course treatment with azoles is associated with a cure rate of 80% to 90% in uncomplicated Candida vulvovaginitis. Male sexual partners may develop Candida balanitis, which typically responds to topical antifungal therapy. Treatment of asymptomatic sexual partners is of no proven benefit.

**EPITHELIAL CELL INFECTIONS**

**Condyloma Acuminata (Genital Warts)**

Principles

Genital warts are caused by human papillomavirus (HPV). More than 40 types of HPV can infect humans, with the majority of HPV infections remaining asymptomatic or unrecognized. Clinically apparent warts occur in approximately 1% of cases. HPV types 6 and 11 cause most cases of visible genital warts and are considered non-oncogenic. HPV types 16 and 18 are responsible for most cases of cervical cancer and are also associated with vaginal, vulvar, anal, penile, and oropharyngeal cancers. Bivalent and quadrivalent HPV vaccines are approved for use in the United States in children, adolescents, and young adults.

Clinical Findings

Genital warts are typically manifested by small painless fleshy papular lesions on the skin or mucous membranes (Fig. 88.9). The slow-growing lesions gradually become more lobulated, pedunculated, or verrucous in appearance. Lesions may become friable and painful due to local irritation or secondary infection. Warts are typically found on the external genitalia, buttocks, and perineum, but they may occur anywhere the organism is inoculated.

Diagnostic Testing

A clinical diagnosis of genital warts is usually made by visual inspection. Differential diagnosis includes molluscum contagiosum, skin tags, nevi, neoplasm, and condyloma lata. Genital warts may have a moist appearance in intertriginous areas, but they do not usually have the denuded surface typically seen with condyloma lata in secondary syphilis. The duration of lesions and presence of associated symptoms are helpful features, because genital warts are often present for months or years but have no associated systemic symptoms. Dark-field microscopy and serology are useful in excluding a diagnosis of syphilis. Although not generally performed in the ED, biopsy can confirm the diagnosis and exclude neoplasm. The application of topical acetic acid to mucosal lesions to screen for HPV is nonspecific and is not recommended.

Management

All available treatments for HPV have significant failure rates. Treatment options include patient-applied regimens and provider-administered regimens. Patient-applied regimens include topical application of imiquimod cream, podofilox solution or gel, or sinecatechins ointment. The patient must be able to adequately visualize and reach the lesions to use these patient-applied agents. These modalities are preferable to some patients, because they can administer the treatment in the privacy of their own home. Provider-administered treatments include surgical excision, cryotherapy, or topical therapy with trichloroacetic acid (TCA) or bichloracetic acid (BCA). Podophyllin-based therapy is contraindicated during pregnancy due to possible teratogenic effects. The emergency clinician may elect to defer initiation of treatment for genital warts and refer the patient to a primary care provider or STD clinic, because the condition is not emergent and a prolonged course of treatment is usually required.

**Molluscum Contagiosum**

Molluscum contagiosum is a localized skin infection caused by a member of the pox virus family. The condition is common in childhood when it is usually acquired via nonsexual contact. It may be sexually acquired in adolescents and adults. Clinical appearance consists of one or more small 2 to 5 mm papules. The lesions have a waxy appearance, and central umbilication is common. Spontaneous resolution typically occurs within 6 to 12 months. Differential diagnosis may include genital warts, skin cancers, nevi, skin tags, and other benign skin lesions. Clinical diagnosis is made based upon the typical appearance of the lesions. No specific diagnostic testing or treatment is necessary in the ED. The patient can be referred to a primary care provider or dermatologist for curettage, cryotherapy, or treatment with topical agents for lesions that persist.
ECTOPARASITES

Pediculosis Pubis

Pediculosis pubis is a parasitic infestation caused by Phthirus pubis, the pubic louse. Although pubic lice are usually sexually transmitted, they can be transmitted via nonsexual contact with infected individuals or contact with infected fomites, such as linen or clothing. Symptoms include pruritus and mild discomfort at the site of the bites. Small erythematous maculopapular lesions with associated punctate bleeding may be seen. The lice are visible in the pubic hair or attached to the skin while feeding. The eggs (nits) are attached to the shaft of the pubic hairs. Diagnosis is confirmed by visual inspection.

Treatment includes topical permethrin 1% creams and rinses which are available over-the-counter. Permethrin should be applied to the affected area and washed off after 10 minutes. Alternative topical agents include pyrethrin shampoo, malathion, and lindane. The patient should attempt to remove any visible nits, because topical treatment is not always ovicidal. Potentially infested linen and clothing should be washed in hot water with detergent. Repeat topical treatment can be applied in 1 to 2 weeks to kill any newly hatched lice. Resistance to pediculicides has been widely reported. An alternative topical agent or oral ivermectin may be used for treatment failures.

Scabies

Sarcoptes scabiei is the mite responsible for scabies. The organism is transmitted via direct person-to-person contact or exposure to infested linens and clothing. Although sexual transmission is common, many cases occur from nonsexual contact. The mite creates superficial burrows in the skin where eggs and excrement are deposited. Intense pruritus is caused by a hypersensitivity reaction to the foreign material in the skin. Careful inspection often reveals characteristic burrows in the skin. Excoriations, papules, and nodules are frequently seen. Commonly affected areas include the groin, genitalia, axilla, and interdigital web spaces of the hands. Diagnosis can be confirmed by microscopic examination of scrapings from characteristic skin lesions, which reveals the mites. The preferred treatment is permethrin 5% cream applied topically and washed off after 8 to 14 hours. Permethrin is nontoxic and can be used safely in pregnancy and in patients of all ages. Alternative agents include topical benzyl benzoate, topical lindane, or oral ivermectin. Linen and clothing should be washed in hot water with detergent.

KEY CONCEPTS

- The ED diagnosis of STDs is often based on clinical findings. Empirical antibiotic treatment is warranted to cover the most likely infecting organisms based upon history and physical examination findings. Rapidly available diagnostic tests (Gram stain, darkfield microscopy, wet mount microscopy, and others) increase diagnostic sensitivity and specificity.
- Confirmatory diagnostic studies (PCR, culture, serology, and others) should be considered even when results are not immediately available. A mechanism for follow-up of test results should be established and appropriate patient contact information obtained.
- STDs frequently coexist. Diagnosis of one STD should prompt consideration and screening for others, including HIV.
- Infection with any STD increases the risk of acquisition and transmission of HIV.
- Genital herpes, the most common ulcerating STD, is often transmitted by persons who are unaware that they are infected or are asymptomatic at the time of transmission.
- Nontreponemal serologic screening tests (VDRL, RPR) may yield false-positive or false-negative results in a patient with a genital ulcer and suspected syphilis.
- In a patient with a genital ulcer, visualization of spirochetes on darkfield microscopy is highly specific for the diagnosis of syphilis and provides rapid confirmatory results.
- Single-dose antibiotic therapy should be used for treatment of STDs when possible. Directly observed therapy administered in the ED enhances treatment compliance.
- A single dose of azithromycin 1g PO will treat chlamydia causing lower genitourinary tract infection (urethritis, cervicitis) but is inadequate for treatment of upper tract infection (PID, epididymo-orchitis).
- A single dose of ceftriaxone 250 mg IM will treat gonorrhea causing both upper and lower genitourinary tract infection in men and women.
- A single dose of long-acting benzathine penicillin G (2.4 million units IM) will treat primary and secondary syphilis.
- A single dose of metronidazole 2g PO is the treatment of choice for symptomatic trichomoniasis during all stages of pregnancy.
- Single-dose antibiotic therapy is inadequate for the treatment of PID.
- HIV, syphilis, gonorrhea, chlamydia, and chancroid are reportable diseases in all 50 of the United States.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
88.1. A 30-year-old pregnant female presents for evaluation of a genital ulcer. Darkfield microscopy reveals spirochetes. She is allergic to penicillin. Which of the following statements is false?

A. Azithromycin is an acceptable treatment alternative for primary syphilis during pregnancy in a patient with known penicillin allergy.

B. Nontreponemal serologic tests for syphilis (rapid plasma reagin [RPR], Venereal Disease Research Laboratory [VDRL]) may yield false negative results in primary syphilis.

C. Primary syphilis facilitates the transmission and acquisition of human immunodeficiency virus (HIV) infection.

D. Syphilis is a reportable disease in all 50 states.

E. The chance of primary syphilis will heal spontaneously without antibiotic therapy.

Answer: A. Penicillin remains the drug of choice for treatment of syphilis during pregnancy. A pregnant patient with syphilis and known penicillin allergy should be admitted for desensitization and treatment with penicillin. Nontreponemal serologic tests may yield false negative results in primary syphilis when antibody titers have not yet risen. False positive serology may be seen with a variety of other medical conditions. Visualization of spirochetes on darkfield microscopy confirms the diagnosis of syphilis. All sexually transmitted diseases (STDs) facilitate the transmission and acquisition of HIV. Reportable STDs in all 50 states include gonorrhea, chlamydia, syphilis, HIV, and chancroid.

88.2. A 17-year-old female presents with complaints of pelvic pain. She reports multiple sexual partners and inconsistent condom use. Pelvic examination reveals yellow cervical discharge, cervical motion tenderness, and bilateral adnexal tenderness. Pregnancy test is negative. Which of the following statements regarding this scenario is correct?

A. All adolescents with pelvic inflammatory disease require hospital admission for intravenous antibiotics.

B. A negative nucleic acid amplification test for gonorrhea and chlamydia reliably excludes the diagnosis of pelvic inflammatory disease.

C. In the absence of an identifiable alternative diagnosis, the clinical diagnosis and empirical treatment of pelvic inflammatory disease is warranted.

D. The clinical diagnosis of pelvic inflammatory disease requires the presence lower abdominal tenderness and cervical motion tenderness and adnexal tenderness on physical examination.

E. Women treated as outpatients for pelvic inflammatory disease should have a follow up evaluation in 2 weeks.

Answer: C. The clinical diagnosis of pelvic inflammatory disease is warranted in a sexually active woman at risk for sexually transmitted diseases (STDs) if no alternative diagnosis is identified and any one of the following findings is present on examination: (1) cervical motion tenderness, (2) uterine tenderness, and/or (3) adnexal tenderness. Additional diagnostic criteria (mucopurulent cervical discharge, fever, elevated white blood count, positive testing for gonorrhea or chlamydia, and others) improve specificity but decrease sensitivity in the diagnosis of pelvic inflammatory disease (PID). Adolescents with PID may be treated as outpatients using the same criteria as adult women. Women receiving outpatient treatment for PID should be advised to seek a follow up evaluation within 48 to 72 hours.

88.3. A previously healthy 22-year-old female is diagnosed with pelvic inflammatory disease (PID). Pregnancy test is negative. She is well-perfused and nontoxic in appearance. She is tolerating oral intake without difficulty. She has no known drug allergies. Which of the following antibiotic regimens is acceptable for outpatient treatment of pelvic inflammatory disease?

A. Azithromycin 1 g per os (by mouth) (PO) (single dose) and metronidazole 500 mg bid for 14 days.

B. Ceftriaxone 125 mg IM (single dose) and doxycycline 100 mg bid for 7 days.

C. Ceftriaxone 250 mg IM (single dose) and azithromycin 1 g PO (single dose).

D. Ceftriaxone 250 mg IM (single dose) and doxycycline 100 mg PO bid for 14 days.

E. Metronidazole 2 g PO (single dose) and doxycycline 100 mg PO bid for 14 days.

Answer: D. Pelvic inflammatory disease is typically a polymicrobial infection. Neisseria gonorrhoeae and/or Chlamydia trachomatis are frequently implicated organisms, but anaerobes, enteric organisms, and normal vaginal flora may also be present. Empirical treatment of PID should include adequate coverage for gonorrhea and chlamydia. A single dose of ceftriaxone 250 mg IM is adequate treatment for upper tract gonococcal infection. A 14-day course of antibiotics is recommended for adequate chlamydia coverage in PID. The addition of anaerobic coverage, such as metronidazole, should be considered.

88.4. A 24-year-old sexually active male presents with painful genital ulcers. Physical examination reveals a cluster of 2...
to 3 mm tender superficial ulcers on the penile shaft. He reports a history of similar lesions in the same location sporadically in the past. Which statement regarding this clinical scenario is false?

A. Both herpes simplex virus (HSV)-1 and HSV-2 can be transmitted through sexual contact.
B. Genital herpes is a lifelong viral infection.
C. Prompt initiation of antiviral medication reduces the duration and severity of symptoms.
D. Topical antiviral therapy is not recommended.
E. Use of condoms is not necessary to prevent transmission in the absence of clinically apparent lesions.

Answer: E. Genital herpes is a lifelong infection caused by herpes simplex virus. Sexual transmission is more common with HSV-2 but may also occur with HSV-1. Condom use is recommended during asymptomatic periods, because viral shedding and transmission may occur even in the absence of clinically apparent lesions. Antiviral therapy is not curative. Prompt initiation of systemic antiviral medication within 72 hours (acyclovir, famciclovir, or valacyclovir) reduces the duration and severity of symptoms, particularly at the time of primary infection. Topical antiviral therapy is not recommended.

88.5. A 24-year-old female presents to the emergency department (ED) complaining of vaginal discharge. A copious frothy whitish discharge is noted on speculum examination. Microscopic examination of a saline wet mount reveals motile flagellated organisms. Which of the following statements is correct?

A. Metronidazole is the drug of choice for treatment of symptomatic trichomoniasis during all stages of pregnancy.
B. Punctate hemorrhagic lesions are seen on the cervix in most cases of trichomonas vaginitis.
C. Tinidazole is a safe alternative for treatment of trichomoniasis during pregnancy.
D. Trichomoniasis is always symptomatic in men and women.
E. Wet mount microscopy approaches 100% sensitivity in the diagnosis of trichomonas vaginitis.

Answer: A. Metronidazole is the drug of choice for treatment of symptomatic trichomoniasis during all stages of pregnancy. Tinidazole should be avoided in pregnant women due to limited data regarding safety for use in pregnancy. Visualization of flagellated protozoans on wet mount microscopy of vaginal discharge is highly specific, but only 50% to 65% sensitive for the diagnosis of trichomoniasis. Punctate hemorrhagic lesions on the cervix (so called “strawberry cervix”) is seen in up to 10% of cases. Nucleic acid amplification tests for trichomonas are highly sensitive and specific. Trichomoniasis may be asymptomatic in men and women.

88.6. Which of the following sexually transmitted diseases (STDs) can be treated with single-dose antibiotic therapy administered in the emergency department (ED)?

A. Chancroid
B. Primary and secondary syphilis
C. Trichomoniasis
D. Urethritis caused by gonorrhea or chlamydia
E. All of the above

Answer: E. Single-dose antibiotic therapy is efficacious for many STDs, including gonococcal urethritis and cervicitis, primary and secondary syphilis, trichomoniasis, and chancroid. Single-dose azithromycin is recommended for coverage of lower genitourinary tract infection with chlamydia. Treatment of upper genitourinary tract STDs, including pelvic inflammatory disease and epididymo-orchitis, requires a longer course of antibiotic therapy. Directly observed therapy administered in the ED promotes compliance.
URINARY TRACT INFECTION IN ADULTS

Urinary tract infection (UTI) is the most frequent bacterial infection occurring more commonly in women than in men. In the United States, the urinary tract is the most common source of infection of patients presenting in septic shock, with an associated mortality of 10% to 20%.

UTI describes an inflammatory response of the urothelium to microorganisms in the urinary tract, resulting in clinical symptoms that include dysuria, frequency, urgency, hematuria, and suprapubic or costovertebral angle discomfort. The diagnosis of a UTI requires the presence of urinary-specific symptoms or signs in a patient who has bacteriuria and no other identified source of infection. Bacteriuria is the presence of bacteria in the urine but is not considered to represent a UTI in the absence of clinical manifestations. Bacteriuria accompanied by symptoms should be treated, whereas bacteriuria in the absence of symptoms should be treated only in select patients (eg, pregnant women, immunosuppressed patients).

UTIs are classified as lower (confined to the bladder) or upper (involving the ureters or kidneys) and as uncomplicated or complicated. An uncomplicated infection occurs in a nonpregnant individual with a structurally and functionally normal urinary tract. A complicated UTI is a heterogeneous term that may be associated with an underlying functional or structural abnormality, history of urinary instrumentation or organ transplantation, or systemic disease, such as renal insufficiency, diabetes, and immunodeficiency. UTIs in men are generally categorized as complicated given the higher incidence of associated urologic abnormalities. However, men can experience a UTI without an underlying structural or functional abnormality. Complicated UTIs often require a prolonged course of antibiotic therapy and a more in-depth approach to testing and anatomic evaluation.

The term urethritis refers to the inflammation of the urethra secondary to an infection or trauma. Frequently, urethritis may be a manifestation of a sexually transmitted disease (STD), such as gonococcal urethritis in Neisseria gonorrhoeae infection, but may occur in other clinical scenarios as well. Cystitis generally refers to inflammation of the bladder resulting in increased urinary frequency, urgency, dysuria, and suprapubic pain. The causes of cystitis can be separated into bacterial and nonbacterial (eg, radiation) categories. Acute pyelonephritis is a UTI involving the renal parenchyma and collecting system, manifesting with the clinical syndrome of fever, chills, and flank pain. Management and disposition of patients with acute pyelonephritis depend on whether the infection is simple or complicated.

Anatomy and Physiology

In women, the urethra is short and opens close to the vulvar and perirectal areas. This contributes to the much higher incidence of UTI in women. The route of infection in men is also usually ascending, from the urethra to the prostate to the bladder and then to the kidney. Risk factors for cystitis and pyelonephritis include sexual intercourse, use of spermicides, previous UTI, new sex partner, and history of UTI in a first-degree female relative.

Pathophysiology

UTIs arise when urinary pathogens from the bowel or vagina colonize the periurethral mucosa and ascend through the urethra and into the collecting system. Infrequently, bacterial infection of the urinary tract arises from hematogenous or lymphatic sources. This is frequently the pathologic mechanism in debilitated and chronically ill patients who are immunosuppressed. Numerous abnormalities of the urinary tract interfere with its innate ability to resist infection. Obstruction from any cause, with resultant stasis of urine, is the major causative factor. Urinary calculi may cause obstruction and increased susceptibility to the development of a UTI.

Subgroups of patients who are more susceptible than the normal population to UTIs include diabetic patients, pregnant women, older adults, patients who are unable to empty their bladder completely, patients with indwelling urinary catheters, and those with immunodeficiency disorders. Lower UTIs are more common in aging men in the setting of prostatic enlargement or obstruction.

*Escherichia coli* is responsible for an estimated 75% to 95% of cases of UTI and pyelonephritis in men and women. Other less common bacteria that may be responsible for infection include *Staphylococcus saprophyticus* and other members of the Enterobacteriaceae family (*Klebsiella pneumonia* and *Proteus mirabilis*). Unusual microorganisms may be found in institutionalized or hospitalized populations. Such settings and conditions predispose the patient to alterations in the normal gastrointestinal (GI) flora, leading to complex UTIs. The uropathogens in these patients include more resistant strains of *Escherichia*, *Klebsiella*, *Proteus*, and *Enterobacter*, as well as *Pseudomonas*, *Enterococcus*, *Staphylococcus*, *Providencia*, *Serratia*, *Morganella*, *Citrobacter*, *Salmonella*, *Shigella*, and *Haemophilus* spp., *Mycobacterium tuberculosis*, and fungi.

Clinical Features

UTI is usually manifested as dysuria, with or without frequency, urgency, hematuria, and suprapubic discomfort. Symptoms of dysuria, frequency, hematuria, nocturia, and urgency all increase the probability of UTI, with likelihood ratios between 1.10 and 1.7, whereas vaginal discharge decreases the likelihood of UTI. The probability of cystitis is greater than 90% in women who have dysuria and frequency without vaginal discharge or irritation. Symptoms of UTI in men may also represent storage or voiding disturbances that are common in aging men (eg, prostatic enlargement). Commonly, men with lower UTIs have symptoms of urinary urgency, frequency, dysuria, hematuria, and suprapubic pain. If fever and chills are present in association with irritative symptoms and difficulty voiding, acute bacterial prostatitis should be strongly considered. A digital rectal examination of the prostate...
gland with attention to size, shape, and consistency can identify prostatic enlargement, inflammation, or cancer.

Clinical signs and symptoms suggestive of pyelonephritis include fever, chills, flank pain, costovertebral angle tenderness, and nausea or vomiting, with or without symptoms of cystitis. The presentation of pyelonephritis can be particularly challenging in those who are debilitated and older adults because they may not be able to verbalize their symptoms and can present without fever; these patients may present with nonspecific complaints such as altered mental status, lethargy, abdominal pain, or generalized weakness.

**Differential Diagnosis**

Bacterial UTI is the most common cause of dysuria. Differential considerations include acute urethritis or acute vaginitis from sexually transmitted infections, as well as mechanical trauma or irritation (Table 89.1). In general, if historical information includes contact with multiple sexual partners, recent change in sexual partners, or sexual partner with dysuria or discharge, *Chlamydia trachomatis* and *N. gonorrhoeae* infection should be strongly considered. Because the diagnosis of UTI is rarer in men, a high suspicion for an STD such as gonococcal or nongonococcal urethritis should be maintained. Trauma, calculi, chemical irritation, candidal infections, psychogenic disorders, neoplasm, and malformations or space-occupying lesions compressing the distal genitourinary tract can also cause dysuria. Older men may have dysuria due to prostatic hypertrophy or prostatitis.

**Diagnostic Testing**

Urinalysis and Urine Culture

A clean-catch, midstream specimen is the preferred type of urine sample for analysis. This is particularly important in woman in whom contamination from the perineum may result in a false-positive test result. However, even when the procedure is performed correctly, a specimen may be contaminated because the surrounding areas can be difficult to clean. A predominance of epithelial cells suggests that the specimen is contaminated. Sterile catheterization is the most accurate method of obtaining a urine specimen in women and may be the best solution for achieving a reliable urinalysis if the patient is unable to provide a clean-catch specimen or is actively menstruating. In men, the specimen is not affected significantly by lack of cleansing or by the timing of specimen collection. Therefore, it is not appropriate to catheterize an adolescent or adult man simply for the purpose of collecting a urine specimen unless he is experiencing urinary retention.

Urine screening tests provide a quick and inexpensive diagnostic tool, with a goal of reliably predicting specimens that will provide positive or negative cultures. The most commonly used screening tests measure urinary leukocyte esterase and nitrite. Both can be detected by a color change on dipstick testing. Leukocyte esterase is an enzyme found in neutrophils, and nitrite is produced from nitrate reductase, present in gram-negative bacteria. However, not all uropathogens, such as *S. saprophyticus* and *Enterococcus*, convert nitrate into nitrite. Dipstick-positive hematuria has also been shown to increase the likelihood for UTI. These findings often are combined to improve overall diagnostic accuracy. A urine dipstick test indicating the presence of nitrite or leukocytes and microscopic blood is moderately sensitive (75%) but less specific (66%) for predicting a UTI. These tests should be used with caution because they can be less sensitive than the microscopic examination of urine (urinalysis). Given the limited negative predictive value of urine dipstick testing, a UTI may be difficult to rule out, even when all features are negative. However, when there is a low pretest probability of UTI, a negative dipstick result for leukocyte esterase and nitrates excludes infection. When the history is strongly suggestive of a UTI and the dipstick is negative, we recommend that a urine culture be sent.

Urine microscopy is an adjunct to the dipstick and helps reduce the number of urine cultures performed. Although no accepted level of pyuria is diagnostic of UTI, careful quantitation with a hemocytometer chamber will find pyuria in nearly all cases of acute UTI caused by coliforms. Pyuria is defined as 10 or more WBCs/mm³. Microscopic examination of urine to identify bacteria remains the most reliable test for a diagnosis of UTI, but is often not available.

The diagnosis of a UTI can be made only with clinical symptoms and the determination of bacteriuria; however, the diagnosis is confirmed with urine culture. The Infectious Disease Society of America (IDSA) defines a positive culture as 10⁵ or more colony-forming units (CFU)/mL. The presence of 10⁴ CFUs/mL of bacteria in a urine culture is associated with a 95% likelihood of infection, whereas 10⁴ CFUs/mL is associated with a 50% likelihood of infection. There is no absolute number of CFUs that is definitive for a UTI; the culture results alone are not diagnostic of infection and must be combined with symptoms suggestive of a UTI. The presence of bacteria on culture in the absence of clinical manifestations does not always indicate infection but may be due to contamination of the specimen.

The decision to perform a urine culture should be assessed for its relevance to patient care. Patients with frequency, dysuria, urgency, and suprapubic pain should be treated on the basis of symptoms, and a urine culture is not required to guide therapy. Patients with relapse or recurrent infections, complicated infection, or those in whom multidrug-resistant organisms are suspected based on previous microbiology or exposure to antibiotics should have a culture performed (Box 89.1).

An STD may mimic a UTI and, in sexually active patients, cultures for *C. trachomatis* and *N. gonorrhoeae* should be considered. Other causes of acute dysuria include infections with *Trichomonas vaginalis* and herpes simplex virus.

**Patient Groups for Whom Urine Culture Is Indicated**

- Children
- Adult men
- Immunocompromised patients
- Patients with treatment failure (ie, with persistent urinary symptoms despite recently completed course of antibiotics)
- Patients with duration of symptoms more than 4 to 6 days
- Older patients at risk for bacteremia
- Ill-appearing patients with signs and symptoms suggestive of pyelonephritis or bacteremia
- Pregnant women
- Patients with known chronic or recurrent renal infection
- Patients with known anatomic urologic abnormalities
- Patients in whom urinary tract obstruction is suspected (eg, stones, benign prostatic hypertrophy)
- Patients with serious medical diseases, including diabetes mellitus, sickle cell anemia, cancer, and other debilitating diseases
- Patients with alcoholism or drug dependence
- Recently hospitalized patients
- Patients taking antibiotics
- Patients who recently have undergone urinary tract instrumentation (eg, cystoscopy, catheterization)

---

**Imaging**

Most patients with acute cystitis or pyelonephritis do not need emergency imaging of the urinary tract. Imaging is reserved for patients with a clinical suspicion for underlying structural abnormalities or complicating factors such as abscess, urolithiasis, or emphysematous pyelonephritis. Patients with pyelonephritis who have severe or worsening illness or persistent fever 48 to 72 hours after the initiation of appropriate antimicrobial treatment should undergo imaging to exclude renal stones, abscesses, or obstruction.

Ultrasoundography is indicated to assess for potential urinary obstruction. Although it is not as sensitive as a contrast computed tomography (CT) scan, it is a sensitive tool for detecting postvoid residual bladder volume, intrarenal and perinephric abscess, and presence of hydroureter and hydronephrosis (Figs. 89.1 and 89.2). Ultrasound can also detect the presence of pyelonephritis and congenital anomalies. Regardless of patient age, this procedure is relatively inexpensive and avoids the hazards of contrast and radiation exposure. A suggestion of obstruction based on clinical suspicion or lack of response to medical therapy necessitates performance of an abdominal ultrasound or noncontrast CT scan.

A contrast CT scan of the abdomen is the most comprehensive initial test for assessing the kidneys, ureters, and bladder. It has a high sensitivity for detecting abscess, obstruction, and acute inflammation. Imaging with an abdominal CT scan is recommended for those with pyelonephritis and known functional or anatomic abnormalities, recent instrumentation, immunosuppression, or concern for obstruction. Its disadvantages include radiation exposure, cost, and potential to induce contrast reactions and acute kidney injury. Contrast-induced complications occur infrequently in patients with a serum creatinine level less than 1.5 mg/dL and can be further avoided by intravenous (IV) hydration with normal saline. CT without contrast can be performed in patients with renal insufficiency and is the preferred study in patients with a clinical concern for urolithiasis.

**Management**

**Simple Urinary Tract Infection**

In 2011, the IDSA released updated clinical practice guidelines for the treatment of uncomplicated cystitis. The options for treating uncomplicated lower UTI include single-dose therapy with fosfomycin, 5 days of nitrofurantoin, or 3 days of trimethoprim-sulfamethoxazole (Table 89.2). Fluoroquinolones such as ciprofloxacin or levofloxacin should not be used as first-line agents for empirical treatment of uncomplicated UTIs. Instead, they should be reserved for patients who have failed first-line therapy or have contraindications. The most recent IDSA guidelines have focused on the unnecessary use of fluoroquinolones for uncomplicated UTIs because the resistance of *E. coli* to ciprofloxacin in the United States has increased from 3% in 2000 to 17% in 2010. In contrast, resistance to nitrofurantoin and fosfomycin has not meaningfully increased since their introduction. The IDSA guidelines acknowledge that cystitis is often a self-resolving infection, with spontaneous symptom improvement occurring in up to 50% of patients. However, there is limited evidence regarding antimicrobial-sparing treatment for UTIs.

Antibiotics should be chosen with local resistance patterns in mind. The IDSA recommends avoiding antimicrobial agents when local resistance exceeds 20%, emphasizing the need to be familiar with local outpatient resistance patterns. Although most
activity against common uropathogens as well as chlamydia and can be used with a single intramuscular dose of ceftriaxone (250 mg) for gonorrhea coverage.

Complex Urinary Tract Infection

Patients with mild to moderate pyelonephritis without complicating factors can be safely treated on an outpatient basis as long as the patient is able to eat and drink, has achieved adequate pain control, and has appropriate social support in the home. Given the risk for systemic illness, bacteremia, and progression to severe sepsis, medications must achieve therapeutic levels not only in the urine but also in the renal tissues and bloodstream. Therefore, fluoroquinolones are the first-line choice (Table 89.3). In areas in which the prevalence of resistance of fluoroquinolones is less than 10%, we recommend a 7-day course of ciprofloxacin for empirical outpatient treatment for uncomplicated pyelonephritis. In areas in which there is more than 10% fluoroquinolone resistance, IDSA guidelines recommend giving a long-acting parenteral antibiotic, such as 1 g ceftriaxone, followed by 10 to 14 days of an oral cephalosporin. Trimethoprim-sulfamethoxazole (TMP-SMX) for 10 to 14 days is an alternative treatment. Nitrofurantoin and fosfomycin do not achieve adequate blood and tissue levels and therefore are not effective for pyelonephritis.

A severe upper tract UTI necessitating hospitalization initially should be treated with parenteral antibiotics, such as cefepime, ceftriaxone, piperacillin-tazobactam, aztreonam, or a fluoroquinolone, with transition to oral therapy after the patient has been afebrile for 24 to 48 hours (Table 89.4).

Nitrofurantoin is an excellent drug for the treatment of acute bacterial cystitis. It is inexpensive and maintains low serum and high urine levels. Nitrofurantoin is effective against *E. coli* but is inactive against other pathogens, such as *Proteus* and *Pseudomonas aeruginosa*. The rate of clearance is proportional to the creatinine clearance, and dose adjustments are necessary with renal impairment. The most common adverse effects of using nitrofurantoin are GI effects, including nausea, vomiting, and diarrhea.

Fosfomycin is appealing for emergency department (ED) use because it can be given as a single dose for simple cystitis and therefore does not require that a patient go to the pharmacy. Fosfomycin is an inhibitor of cell wall synthesis, structurally unrelated to any other antibiotic, and is active against most urinary tract pathogens. Both nitrofurantoin and fosfomycin remain effective against extended-spectrum, ß-lactamase–producing bacteria.10

A useful adjunctive therapy for UTIs is phenazopyridine (Pyridium). It produces topical analgesia in the urinary tract and helps relieve dysuria. Patients should be cautioned that body secretions and excretions (eg, tears, urine) will turn orange. This side effect can stain contact lenses and alarm unknowing patients.

The clinical presentations of UTIs and STDs can overlap and, at times, empirical treatment must be directed at both possibilities. In these cases, levofloxacin (500 mg/day for 7 days) has activity against common uropathogens as well as chlamydia and can be used with a single intramuscular dose of ceftriaxone (250 mg) for gonorrhea coverage.
Oral therapy should be continued for 2 weeks. Because 20% of cultures are resistant to ampicillin, cephalothin, and sulfonamides, antibiotic therapy should be initiated with a fluoroquinolone. Follow-up urine cultures are recommended given the diverse flora and high rate of antimicrobial resistance.

In men, if there are no signs of toxicity, the patient can be treated on an outpatient basis with any of the urinary antibacterial agents (eg, TMP-SMX, nitrofurantoin, fluoroquinolones) for 7 to 14 days. If concomitant prostatitis is suspected, TMP-SMX or a fluoroquinolone is recommended for 14 days. If evaluation demonstrates suspicion for prostate involvement, recurrent infection, or hematuria, the patient should be referred to a urologist for further evaluation. Patients with symptoms of prostatic enlargement can be treated with α-adrenergic receptor antagonists and/or 5-alpha-reductase inhibitor therapy (Table 89.5). Surgical treatment produces the most significant, long-term symptom improvement; it includes transurethral prostate resection, open prostatectomy, laser vaporization, transurethral microwave therapy, or needle ablation. Decisions regarding treatment options are based on the degree of obstruction and symptoms.

Disposition. Hospitalization is required in the presence of clinical toxicity (eg, fever, tachycardia, hypotension, vomiting), inability to take oral medications, an immunocompromised state, third-trimester pregnancy, failure of oral outpatient therapy, urologic abnormalities, or patients with significant comorbid conditions, including heart failure and renal insufficiency. A subgroup of patients with an upper tract UTI do not require immediate hospital admission but may benefit from IV hydration and pain and fever control, along with a first dose of an IV fluoroquinolone before discharge from the ED. Chapter 66 discusses the use of ED observation units for this type of care. If these patients do not have any contraindications, as previously discussed, improvement; it includes transurethral prostate resection, open prostatectomy, laser vaporization, transurethral microwave therapy, or needle ablation. Decisions regarding treatment options are based on the degree of obstruction and symptoms.

Complicated Urinary Tract Infection in High-Risk Populations

**Pregnancy.** UTI during pregnancy represents a special situation. Although the incidence of UTI in pregnancy is approximately the same as in nonpregnant women, pyelonephritis is more common during pregnancy. This is likely a result of the physiologic changes that occur within the urinary tract of pregnant women, which include ureteral and renal pelvis dilatation. Factors associated with a higher risk of bacteriuria include a history of prior urinary tract infection, preexisting diabetes mellitus, increased parity, and low socioeconomic status.

Unlike bacteriuria in nonpregnant females, bacteriuria in pregnant women, even if they are asymptomatic, should be treated. Untreated bacteriuria in pregnancy is associated with premature labor, low birth weight, perinatal mortality, maternal anemia, and maternal pyelonephritis. Like nonpregnant women, E. coli is the most common uropathogen. The symptoms of UTI and pyelonephritis are also the same as in nonpregnant patients; however, urinary frequency and urgency may be symptoms of a normal pregnancy. Specimen collection and diagnostic strategies are also similar. A urine culture specimen should be obtained, along with a follow-up culture as a test of cure.

Options for empirical treatment for UTI include amoxicillin-clavulanate, cefpodoxime, nitrofurantoin, fosfomycin, and TMP-SMX (Table 89.6). TMP-SMX and nitrofurantoin should be avoided during the first trimester. TMP-SMX is associated with teratogenic risk and nitrofurantoin may cause fetal malformations when used in the first trimester. Both medications should also be avoided during late pregnancy because TMP-SMX can cause kernicterus, and nitrofurantoin may precipitate hemolytic anemia when used after 37 weeks. Fluoroquinolones should be avoided in pregnancy.

Hospital admission should be considered for patients in their last trimester, who appear ill, or who have evidence of pyelonephritis and would benefit from treatment with parenteral antibiotics and IV fluids. Parental regimens for the empirical treatment of pyelonephritis are similar to those for nonpregnant patients, except the use of fluoroquinolones, and include ceftriaxone, cefepime, aztreonam, and piperacillin-tazobactam (Table 89.7). Nitrofurantoin and fosfomycin do not achieve tissue levels adequate to treat pyelonephritis appropriately. Hospitalized pregnant patients who are afibrile for 48 hours can be discharged on oral antibiotics, directed by culture susceptibility results, to be completed in 10 to 14 days.

Indwelling and Temporary Urinary Catheters. Guidelines published by the IDSA have defined catheter-associated UTI (CAUTI) as the presence of symptoms (eg, new onset or worsening of fever, rigors, altered mental status, malaise, or lethargy with
no other identified cause; flank pain, costovertebral angle tenderness, acute hematuria; or pelvic discomfort) and more than 1000 CFU/mL of one or more bacterial species. Screening for or treating asymptomatic bacteriuria in patients with indwelling catheters is not indicated.

Antibiotic treatment results in the development of resistant microorganisms, whereas removal of the catheter leads to the spontaneous elimination of bacteria in many patients. Treatment of patients with a UTI in whom removal of the catheter is contraindicated includes urine culture and sensitivity, antibiotic therapy, replacement of the catheter, and strong consideration for hospitalization in those who exhibit altered vital signs, systemic symptoms, or a toxic appearance.

Many patients with indwelling urinary catheters who present to the ED are older and not able to verbalize their symptoms or lack clinical signs of infection. Given that a catheter-associated UTI is a common cause of subsequent bacteremia and mortality, empirical antimicrobial therapy, in addition to replacement or removal of the catheter, is often appropriate in such patients. Urine culture with antibiotic sensitivity testing will help guide antibiotic therapy in this patient population. The most important risk factor for bacteruria is the duration of catheterization. The most effective strategy for addressing CAUTIs is to prevent the infection from occurring by placing urinary catheters only when indicated and considering the use of intermittent catheterization and condom catheters, when appropriate.

**PROSTATITIS**

More than 90% of men with febrile UTIs show involvement of the prostate. Prostatitis encompasses four distinct clinical processes—acute bacterial prostatitis, chronic bacterial prostatitis, chronic prostatitis–chronic pelvic pain syndrome, and asymptomatic inflammatory prostatitis. Acute bacterial prostatitis generally affects men between the ages of 20 and 40 years, with a second peak in men older than 60 years. Acute prostatitis is caused by a bacterial infiltration that is usually precipitated by reflux of urine infected by *E. coli, Klebsiella, Enterobacter, Proteus, or Pseudomonas* spp.

Chronic bacterial prostatitis is a persistent bacterial infection of the prostate lasting more than 3 months. Approximately 10% of acute bacterial prostatitis cases develop into chronic bacterial prostatitis. This can be caused by undertreated acute bacterial prostatitis or highly virulent strains. Like acute bacterial prostatitis, gram-negative bacteria are responsible for most cases of chronic prostatitis.

Of patients with chronic bacterial prostatitis, 10% will develop chronic pelvic pain syndrome (CPPS). CPPS is defined as urologic pain in the pelvic region associated with urinary symptoms or sexual dysfunction lasting for at least 3 of the previous 6 months. CPPS is not associated with current infection, malignancy, or structural abnormality. Symptoms of chronic bacterial prostatitis may not differ from those of CPPS. It is a heterogeneous condition with broad diagnostic criteria and uncertain cause, making it difficult to determine an effective treatment regimen reliably.

**Clinical Features**

Patients with acute prostatitis often report UTI symptoms such as fever, chills, dysuria, urinary frequency or urgency, and/or perineal and lower back pain. A rectal examination will reveal an exquisitely tender and swollen prostate gland in more than 90% of patients. There is no evidence that performing a rectal examination induces clinically significant bacteremia.

Clinical manifestations of chronic prostatitis vary widely, making recognition difficult. Most patients report some degree of voiding symptoms (e.g., frequency, urgency, dysuria), low back and perineal pain and, occasionally, myalgias. Fever and chills are uncommon except during an acute exacerbation of the chronic infection. Findings on the physical examination, including examination of the prostate, often are unremarkable. The diagnosis is based on history, physical examination, and positive urine culture.

**Diagnostic Testing**

Acute bacterial prostatitis is a clinical diagnosis. A urine Gram stain and culture are recommended to identify causative organisms and guide treatment. Blood cultures are recommended for patients with acute prostatitis and fever who have not yet received antibiotics. Although acute bacterial prostatitis is usually caused by typical urinary pathogens, an STD such as chlamydia and gonorrhea should be considered, especially in sexually active patients. Urinalysis and culture or DNA amplification, should be obtained if an STD is suspected.

The most common complications of acute prostatitis are acute urinary retention and prostatic abscess. Approximately 10% of men with acute prostatitis will have some urinary retention, which can be diagnosed using bedside ultrasound. Transrectal ultrasound or CT can detect prostatic abscess and should be considered in patients who fail to improve with antibiotics.

**Fig. 89.3.** Prostate abscess. B, Bladder; P, prostate; R, rectum. (From Vandevor JC, Patel N, Dalawari P: Prostatic abscess. J Emerg Med 2011;40: e83–e85, 2011.)
Management

Outpatient therapy can be used if the patient is not systemically ill, can tolerate oral medications, and does not have urinary retention. General support measures for outpatients should include bed rest, analgesics, nonsteroidal antiinflammatory drugs (NSAIDs), hydration, and stool softeners. Alpha blocker therapy is also recommended for obstructive voiding symptoms related to prostatitis (see Table 89.5).

There is no consensus regarding an optimal treatment regimen, so regional patterns of antibiotic resistance should be considered. Few antimicrobial agents are able to penetrate the prostate and achieve sufficient concentrations to eradicate infection. Fluoroquinolones, such as ciprofloxacin or levofloxacin, achieve the highest concentrations in the prostate and are the first-line agents in the treatment of bacterial prostatitis. Empirical parenteral antibiotics such as ciprofloxacin, levofloxacin, or ceftiraxone are recommended until fever and other symptoms have subsided. After improvement, oral antibiotics are recommended for at least 4 weeks (Table 89.8). If an STD is suspected, azithromycin can treat both chlamydia and gonorrhea.

If the patient appears systemically ill, cannot tolerate oral medications, or has urinary retention, hospitalization and parenteral antibiotics are warranted. Treatment options include ciprofloxacin 400 mg IV every 12 hours, levofloxacin 500 mg IV every 24 hours, or ceftiraxone 2 g IV every 24 hours, with or without gentamicin, 3 to 5 mg/kg per day. Following clinical improvement, the patient may be transitioned to an oral regimen, such as a fluoroquinolone. The duration of treatment should be a minimum of 2 weeks, although 4 to 6 weeks may be necessary.

The treatment of chronic bacterial prostatitis consists of antibiotics for 4 to 12 weeks (see Table 89.8). Of the researched treatments, α-adrenergic receptor blockers and antibiotics used alone or in combination result in the greatest improvement in symptoms. Antiinflammatories may also be beneficial. Patients thought to have chronic prostatitis or CPPS should be referred to a urologist.

Treatment of prostatic abscess consists of broad-spectrum intravenous antibiotics (eg, ciprofloxacin, 400 mg IV every 12 hours) and urologic consultation for perineal drainage or surgical debridement.

RENAL CALCULI

Multiple pathogenic factors interact to cause the formation of renal calculi. Risk factors include older age, male gender, obesity, and family history (Box 89.2). Its incidence depends on geographic, ethnic, dietary and genetic factors. It affects up to 20% of the population worldwide, and recurrence rates are close to 50%. In the United States, prevalence rates for renal calculi are 11% in men and 7% in women; the incidence of kidney stones has continued to rise in all age groups and genders. Nearly 70% of all ureteral calculi occur in individuals aged 20 to 50 years, with an increased prevalence reported in areas with hot or dry climates.

Pathophysiology

Most ureteral calculi originate in the kidney and then pass into the collecting system. The chemical composition of urinary tract stones is the key factor for determining optimal management. Stone are generally composed of calcium, struvite, or uric acid. Most stones (75%) are composed of calcium oxalate, alone or in combination with calcium phosphate. The hyperexcretion of calcium is a major contributor to stone formation; its most common identified cause is hyperparathyroidism. Other medical conditions that lead to increased calcium levels include hypercalcemia of malignancy, sarcoidosis, and excessive calcium ingestion or increased absorption from the gut. The other major component of calcium stones, oxalate, is influenced by diet. Hyperoxaluria occurs in the presence of small bowel disease, bariatric surgery, Crohn’s disease, ulcerative colitis, and radiation enteritis.

Magnesium ammonium phosphate (struvite) stones account for approximately 15% of all renal calculi. Struvite stones occur almost exclusively in patients with UTIs and often are referred to as infection stones. They form as a result of the presence of urea-splitting organisms, such as Proteus, Providencia, Klebsiella, Pseudomonas, and Staphylococcus. Patients with anatomic abnormalities that predispose them to recurrent UTIs are at increased risk of developing struvite stones. Most staghorn calculi—stones that fill the greater part of the collecting system—are composed of struvite.

Uric acid stones account for 10% of all stones in the United States. Approximately 15% of patients with symptomatic gout have uric acid calculi, and the incidence of uric acid stones increases with the use of uricosuric agents. In addition to hyperuricosuria, aciduria is considered necessary, because the precipitation of uric acid is unlikely at a higher urine pH. A distinctive feature of uric acid stones is their radiolucency.

Impaction along the genitourinary tract is a serious complication of renal calculi and can cause several physiologic changes. Once obstruction occurs, a rapid redistribution of renal blood flow causes the kidney to preserve urine formation in the nonobstructed side.

BOX 89.2

Risk Factors for Urolithiasis

- Metabolic disease or disturbance
- Crohn’s disease
- Milk-alkali syndrome
- Primary hyperparathyroidism
- Hypernatriuria
- Hyperuricosuria
- Sarcoidosis
- Recurrent UTI
- Renal tubular acidosis (type I)
- Gout
- Laxative abuse
- Positive family history
- Hot arid climates (southeast United States)
- Male gender (white men affected more commonly than black men)
- Previous kidney stone
- Dehydration

UTI, urinary tract infection.
flow results in a decrease in the glomerular filtration rate (GFR). As glomerular and tubular function decrease, renal excretion shifts to the unaffected kidney. Obstruction also causes a rapid decrease in ureteral peristaltic activity. In the presence of infection, renal and ureteral function may be impaired. Complete obstruction of the ureters may lead to loss of renal function, with an increased incidence of irreversible damage after 1 to 2 weeks, including rupture of the renal calyx. Partial obstruction is associated with a lower likelihood of renal injury, but may still result in irreversible damage.

Although calculus size and location are important determinants of the degree of disease, the major cause of progressive renal damage is associated infection. The stone behaves as a foreign body and leads to stasis and obstruction, decreasing host resistance and increasing the incidence of infection. Subsequent infectious complications include pyelonephritis, perinephric abscess, and gram-negative bacterial sepsis.

The three primary predictors of stone passage without the need for surgical intervention are calculus size, location, and degree of patient pain. The most important factor that relates to passage of a calculus though the genitourinary tract is its size. Approximately 90% of stones smaller than 5 mm pass spontaneously within 4 weeks. This percentage decreases to 15% for stones 5 to 8 mm in size. Up to 95% of stones larger than 8 mm become impacted along the genitourinary tract, and lithotripsy or surgical removal may be required. Surgical intervention can be performed on an outpatient basis, provided the patient is able to tolerate oral intake and has adequate pain control unless the stone is infected, renal damage is considerable, there are bilateral obstructing stones, or there is obstruction of a solitary or transplanted kidney. Spontaneous passage is more frequent with stones located below the midureter than those located above the midureter.

Renal calculi seldom cause complete obstruction. There are five sites along the ureter at which calculi are likely to become impacted (Fig. 89.4). First, a stone may lodge in the calyx of the kidney or pass into the renal pelvis and become lodged at the ureteropelvic junction. The relatively large renal pelvis (1 cm) narrows abruptly at its distal portion, where it is equal in diameter to its adjoining ureter (2–3 mm). The third region is near the pelvic brim, where the ureter arches over the iliac vessels posteriorly into the true pelvis. The most constricted area along the ureter, and a common location for impaction, is the ureterovesicular junction. This is the site at which the ureter enters the muscular coat of the bladder (intramural ureter). At the time of diagnosis, up to 75% of stones are located in the distal third of the ureter. Finally, calculi may become lodged in the vesical orifice.

**Clinical Features**

The onset of pain usually is abrupt, with a crescendo of extreme pain that begins in the flank, extends laterally around the abdomen, and radiates into the groin. Pain may radiate to the testicles in men and the labia majora in women. A constant, underlying dull ache in the flank is common between episodes of colic. The cause of colicky, severe flank pain is hyperperistalsis of the smooth muscle of the calyces, pelvis, and ureter, whereas the cause of a dull ache can be acute obstruction and renal capsular tension. GI symptoms of nausea and vomiting are common.

One-third of patients experience gross hematuria, with or without blood clots in the urine. Symptoms of urinary urgency and frequency often develop as the stone nears the bladder. A history of fever and chills strongly suggests superimposed infection; these cases should be regarded as true urologic emergencies.

A patient with renal colic often is in severe pain and paces or writhes in pain on the stretcher, unable to find a comfortable position. Fever, if present, strongly suggests infection. The abdomen should be auscultated and palpated in search of bruits and thrills over the abdominal aorta and iliac vessels because the clinical manifestations of aortic abdominal aneurysms may mimic those of renal colic. Patients commonly have intermittent pain that may nearly resolve between episodes of severe discomfort.

**Differential Diagnosis**

A number of clinical diseases can produce pain similar to that of renal colic (Box 89.3). Potentially serious or life-threatening alternate diagnoses include pulmonary embolism, ectopic pregnancy, bowel obstruction, incarcerated inguinal hernia, pancreatitis, cholecystitis, renal vein thrombosis, and renal malignancies and infarction. One review of consecutive CT reports for patients presenting to an ED with acute flank pain has shown the most common alternate diagnoses to be biliary disease, appendicitis, pyelonephritis, ovarian cyst, renal mass, and abdominal aortic aneurysm (AAA), with and without rupture.

**Diagnostic Testing**

**Urinalysis and Culture**

Red blood cells (RBCs) generally are found in the urine of patients with urolithiasis. However, the absence of RBCs in the urine does not exclude the diagnosis. Up to 20% of patients with documented urolithiasis have no microscopic hematuria. Furthermore, there is no correlation between the degree of obstruction and absence of hematuria.

Sterile pyuria can occur in the absence of infection as a result of ureteral inflammation, but the presence of a UTI should be investigated if other clinical signs of infection are present, such as...
Selected Urologic Disorders

CHAPTER 89

Differential Diagnosis for Pain Associated With Urolithiasis

**UROLOGIC DISEASE**

**Upper Urinary Tract**
- Renal infarct
- Renal parenchymal tumors
- Urothelial tumors
- Papillary necrosis
- Pyelonephritis
- Hemorrhage (blood clot)

**Ureter**
- Urothelial tumors
- Hemorrhage (blood clot)
- Previous surgery (eg, stricture)
- Metastatic tumors

**Lower Urinary Tract**
- Urothelial tumors
- Urinary retention

**NONUROLOGIC DISEASE**

**Intra-abdominal**
- Peritonitis (especially appendicitis)
- Biliary colic
- Intestinal obstruction

**Vascular**
- Abdominal aortic aneurysm
- Superior mesenteric artery occlusion

**Retroperitoneal**
- Retroperitoneal lymphadenopathy
- Retroperitoneal fibrosis
- Tumor

**Gynecologic**
- Cervical cancer
- Endometriosis
- Ovarian vein syndrome

**Musculoskeletal**
- Muscle strain or bony injury

fever and chills. A urinalysis with culture should be performed to look for pyuria and bacteriuria and to measure nitrite and leukocyte esterase levels when infection is suspected.

The kidney does not produce urine with a pH greater than 7.5 under normal conditions, so a urinary pH higher than 7.5 should raise suspicion for the presence of urea-splitting organisms such as *Proteus*. Renal tubular acidosis and ingestion of absorbable alkali also may increase the urinary pH and should be considered in the differential diagnosis. A pH less than 5 often is associated with the formation of uric acid calculi.

**Other Laboratory Tests**

Measurement of blood urea nitrogen (BUN) and serum creatinine levels is not routine but should be performed in patients who have a renal calculus with a solitary kidney, transplanted kidney, or history of renal insufficiency. On rare occasions, urolithiasis can present as acute renal failure resulting from obstruction of both ureters or the ureter of a solitary kidney. A slightly elevated white blood cell (WBC) count in patients with renal calculi may be the result of demargination from acute pain, but this is not a sensitive test and should be performed only in patients who are thought to be infected. A significantly elevated WBC count or left shift on the differential suggests active infection.

**Imaging**

Imaging is not needed in all patients with renal colic but should be performed when signs and symptoms are atypical and the diagnosis is in question, the patient has a solitary or transplanted kidney, or appears toxic, or high-grade obstruction is suspected.

**Radiography of the Kidney, Ureter, and Bladder.** As an initial imaging study, kidney, ureter, and bladder (KUB) radiography provides only presumptive evidence of calculi (<70% specificity), so it should be followed by a more definitive study or avoided altogether. A KUB film is the standard initial radiographic study done before injection of contrast medium during IVP (Figs. 89.5 and 89.6). It is of limited usefulness on its own except as a progress film after CT has already identified a radiopaque stone.

**Intravenous Pyelography.** Intravenous pyelography is an accurate imaging modality to detect renal stones, but is seldom used now because CT scanning and ultrasonography have become first-line imaging modalities. It is very sensitive, capable of establishing the diagnosis of calculous disease in 96% of cases, and it can quantify the presence and severity of obstruction.

**Computed Tomography.** Non–contrast-enhanced helical (spiral) CT scanning is the standard imaging modality in the United States. It is 98% sensitive and 97% specific, with a negative predictive value of 97%, in detecting ureteral calculi and ureteral
Management

The first priority for a patient with a presumed diagnosis of kidney stone is adequate pain control. NSAIDs are first-line agents, but parenteral administration often is necessary because of nausea and vomiting. Ketorolac, 30 mg IV, or diclofenac, 75 mg intramuscularly (IM), provide rapid effective analgesia and decrease ureterospasm and renal capsular pressure by diminishing the GFR in the obstructed kidney. Accordingly, caution is advised with use of these agents in patients with underlying renal insufficiency or peptic ulcer disease. An IV narcotic such fentanyl (1–2 µg/kg) is also very effective in providing rapid analgesia. The combination of NSAIDS and opiates may reduce length of stay in the ED. In the patient who is unable to tolerate oral fluids, IV fluids and an antiemetic such as ondansetron, 4 mg IV, should be given. There have been no definitive studies proving that high-volume fluid therapy in those with acute renal colic facilitates stone passage or improves outcomes.

Concomitant infection with an obstructive stone and hydronephrosis constitutes a true urologic emergency and may warrant immediate urologic intervention for placement of ureteral stents or decompression of the renal pelvis by percutaneous nephrostomy.

Disposition

Indications for Admission

Hospitalization is recommended for patients who are severely dehydrated, are experiencing unrelenting pain or vomiting, or obstruction. Rarely, some kidney stones may be radiolucent (such as those found in HIV patients on protease inhibitors). Other advantages include its ability to detect calculi as small as 1 mm in diameter and provide direct visualization of complicating conditions such as hydroureter, hydronephrosis (Fig. 89.7), and ureteral edema.

The CT scan is superior to alternate imaging modalities in its ability to recognize other pathologies, such as malignancy, renal abscess, and AAA. Other advantages include lack of contrast exposure, short duration of testing, and ease of interpretation. For patients with a body mass index less than 30 kg/m², low radiation dose protocols can be used, with sensitivities and specificities still reported as more than 90%.

Most patients with a history of nephrolithiasis and clinical picture consistent with renal colic should not undergo any form of imaging. Imaging is appropriate in patients with a history of nephrolithiasis who do not improve with treatment, have a urinalysis showing infection, have a solitary or transplanted kidney, or in whom a diagnosis other than renal colic is suspected.

Ultrasonography. Compared to CT, renal ultrasonography is associated with lower cumulative radiation exposure and shows similar results in factors such as identifying other high-risk diagnoses with complications, serious adverse events, pain scores, return ED visits, and hospitalization. It is safe and easily performed, but is much less reliable than CT scanning for detecting small (<5 mm in diameter) ureteral and midureteral stones.

Although only 45% sensitive for detecting calculi, ultrasound examination shows hydronephrosis with a sensitivity of 85% to 94% and specificity of 100% (Fig. 89.8). It is the study of choice for ruling out hydronephrosis in a pregnant patient with pyelonephritis, if obstructive urolithiasis is a concern, or in obese patients who cannot undergo CT scanning.

Fig. 89.6. In a near-term pregnant woman with an obstructed left kidney, this intravenous pyelogram demonstrates a delayed nephrogram. The right kidney has physiologic hydronephrosis from ureteral compression by the fetal head.

Fig. 89.7. CT scans obtained in a patient with renal colic. A, Right-sided hydronephrosis. B, Right ureteral calculi.
have an underlying urinary infection (Box 89.4). Sepsis and renal damage are risks in the presence of obstruction and infection, so these patients require an emergent urologic consultation to evaluate the need for immediate operative intervention to provide drainage and relieve the obstruction. If signs of sepsis (eg, tachycardia, fever, hypotension, shock) are present, ceftriaxone, 1 g IV, should be given and fluid resuscitation carried out pending urologic evaluation.

Several interventional strategies are available to the urologist for the management of stones that do not pass spontaneously.

**BOX 89.4**

**Indications for Hospitalization of Patients With Urolithiasis**

**ABSOLUTE**
- Obstructing stone with signs of urinary infection
- Intractable nausea or vomiting
- Severe pain requiring parenteral analgesics
- Urinary extravasation
- Hypercalcemic crisis

**RELATIVE**
- Significant comorbid illness complicating outpatient management
- High-grade obstruction
- Leukocytosis
- Solitary kidney or intrinsic renal disease
- Psychosocial factors adversely affecting home management

Optimal therapy depends on the size, location, and composition of the stone. Ureteroscopy and extracorporeal shock wave lithotripsy (ESWL) are the two most commonly used techniques. A Cochrane review has found that ureteroscopic removal of ureteral stones, compared to ESWL, achieves a greater stone-free state and lowers the need for retreatment, but is associated with a higher complication rate and longer hospital stay. Percutaneous nephrolithotomy, which establishes a tract from the skin to the collecting system, is used for stones too large or hard for ESWL or ureteroscopy by removing them directly from the renal pelvis.

**Outpatient Management**

Most patients with nephrolithiasis may be safely managed as outpatients. They should be instructed to return to the ED immediately for intractable or severe pain, persistent nausea and vomiting, fever or chills, or difficulty voiding. Spontaneous passage usually occurs within 4 weeks after the onset of symptoms. Patients with first-time stones or those who have not had chemical analysis of their stones should strain all urine or simply void into a glass jar; the calculus should be visible at the bottom. The stone can be submitted to the follow-up urologist for analysis. If a stone has not been passed within 4 weeks, intervention is indicated, because the risk of complications such as ureteral stricture and renal function deterioration increase. The patient should be instructed to drink a moderate amount of fluids, take analgesics as needed for pain, and engage in activity as tolerated.

Medical expulsive therapy is another potentially useful treatment modality for the management of distal ureteral stones smaller than 10 mm. $\alpha_1$-Antagonists (eg, tamsulosin, 0.4 mg PO daily) promote spontaneous passage of distal ureteral stones.

Note: No single finding in patients with an acute scrotum can reliably differentiate torsion from other causative disorders. When torsion is a diagnostic possibility, prompt urology consultation and further testing are mandatory.

daily) and calcium channel blockers (eg, Nifedipine XR 30 mg PO daily) facilitate distal stone expulsion and decrease the time to spontaneous stone passage by blocking ureteral smooth muscle contraction and improving antegrade stone movement. Although both have been shown to increase the stone expulsion rate, greater evidence exists for alpha blockers. A recent Cochrane review has concluded that alpha blockers reduce the episodes of colic, need for analgesic medication, and hospitalization. Mild side effects, such as dizziness, palpitations, headache, rhinitis, retrograde ejaculation, fatigue and asthenia, cutaneous reactions, and postural hypotension, rarely require cessation of therapy. Both the European Urological Association (EAU) and American Urological Association (AUA) recommend alpha blockers for the expulsion of distal ureteral stones when there is no indication for immediate surgical stone removal.

BLADDER (VESICAL) CALCULUS

Approximately 5% of calculi originate in the bladder. Bladder stones occur almost exclusively in older men, often as a complication of an infection of residual bladder urine with urea-splitting organisms or an indwelling catheter. Other disorders predisposing to the formation of bladder stones include bladder neck obstruction (usually secondary to prostatic hyperplasia), neurogenic bladder, vesical diverticula, damage from irradiation, and schistosomiasis.

Clinical Features

Bladder stones cause pain on voiding and hematuria. The patient may report a sudden interruption of the urinary stream, which strongly suggests a vesical stone that intermittently obstructs the bladder outlet. Frequency, urgency, and dysuria are described by up to 50% of patients, and UTIs are common.

The physical examination is rarely helpful; the rectal examination may reveal an enlarged prostate or prostatic malignancy. Poor sphincter tone may suggest a neurogenic bladder.

Diagnostic Testing

Urinalysis generally reveals pyuria, bacteriuria, and hematuria. Plain radiographs of the pelvis reveal a bladder stone in 50% of cases. Contrast scans may demonstrate obstructive changes in the upper tracts or bladder diverticula. Ultrasonography also is useful in the diagnosis of bladder stones.

Management

Surgery is currently the gold standard of care. Depending on the size of the stone, an endoscopic or open approach is used.

ACUTE SCROTAL PAIN

The most common causes of acute scrotal pain are epididymitis and torsions of the testicle and testicular appendage (Table 89.9). A delay in treatment of testicular torsion beyond 6 hours is associated with an increased risk of testicular loss and infertility (Fig. 89.9). Box 89.5 lists a number of other disorders that can present as scrotal pain. Some are emergent surgical conditions such as Fournier’s gangrene and incarcerated hernias, whereas others require less invasive and time-dependent therapies, such as antibiotics for epididymitis and observation for benign masses or torsion of the appendix of the testes.

Fig. 89.10 demonstrates the anatomy of the scrotum and testis. A normal scrotum is relatively symmetric, and both testicles are of equal mass and volume. The left testicle often is higher than the right because its blood flow empties into the large, low-pressure vena cava, whereas the right drains into the relatively smaller, high-pressure renal vein. A normal testis is found in the vertical axis with a slight forward tilt, and the epididymis is above the superior pole in the posterolateral position. The epididymis is located posterolateral to the testis and is normally nontender and soft. The cremasteric reflex is elicited by stroking or pinching the inner aspect of the thigh; more than 0.5 cm of elevation of the ipsilateral testis is considered evidence of a normal reflex. This reflex normally is absent in 50% of male infants younger than 30 months.

Specific Disorders

Testicular Torsion

Testicular torsion is present in 3% to 17% of children brought to the ED with scrotal pain. It has a bimodal incidence in the first
year of life and at puberty, when the rapid increase in testicular volume predisposes the testis to torsion (Fig. 89.11). Up to 40% of cases occur in adults. It is more common in the winter months, presumably because low ambient temperature induces contraction of the cremasteric muscles.

With torsion, a congenital defect of the testis results in abnormal testicular rotation during cremasteric contraction. This leads to twisting of the spermatic cord, resulting in obstruction of venous outflow, subsequent compromised arterial flow, and testicular ischemia. Torsion from the most common congenital defect resembles the ringing of the clapper in a bell—hence, the description of a so-called bell clapper deformity.

Testicular salvage hinges on the degree of torsion and duration of the ischemia. Torsion that presents to the ED within 6 hours is associated with testicular salvage rates of 80% to 100%, whereas symptoms persisting for longer than 6 hours are as low as 44%.

**Fig. 89.9** Testicular salvage and atrophy rates over time in testicular torsion. **A,** Immediate (early) surgical salvage after torsion. **B,** Subsequent atrophy of surgically salvaged testes after torsion at various time intervals. Clinical Features. Patients typically report a sudden onset of rapidly escalating pain in the scrotum, lower abdomen, or inguinal area that awakens them from sleep or develops several hours after physical activity. Although a short time from the onset of symptoms to presentation favors torsion, it cannot be reliably used to differentiate it from other causes of scrotal pain. In one large study, 72% of torsion patients presented more than 12 hours after the onset of their symptoms.28 Up to 29% of patients with testicular torsion describe similar pain in the past, caused by previous intermittent torsion in a predisposed testicle. Patients often report nausea and vomiting or abdominal pain caused by reflex stimulation of the celiac ganglion.29 Because up to 10% of torsion cases may present with abdominal pain and no scrotal pain, the scrotum should be examined in all patients presenting with abdominal pain.

A history of scrotal trauma reduces a patient’s likelihood of having testicular torsion; however, approximately 10% of patients with testicular torsion report prior acute blunt trauma to the scrotum.25 In these cases, the symptoms of torsion often are misattributed to the trauma itself, delaying the diagnosis and worsening the rate of testicular salvage.

The physical examination is much more reliable than the history in determining the presence of testicular torsion. The cremasteric reflex is usually absent in patients with torsion; however, its presence cannot be used to rule out torsion. Patients with torsion frequently have a tender firm testicle that can be palpated in the transverse position and displaces the epididymis from its usual location along the posterior aspect of the scrotum. Often, the patient’s scrotum is so swollen and tender that a complete physical examination is impossible. After 24 hours, the physical examination is not particularly helpful because many of the aforementioned findings are no longer present.

Differential Diagnosis. There is no single history or physical examination finding that accurately or reliably differentiates torsion from other causative disorders (see Table 89.9). Any patient with acute onset of scrotal pain in whom the diagnosis of torsion cannot be ruled out should undergo further diagnostic testing.

Diagnostic Testing

Urinalysis. In patients in whom the history and physical findings strongly suggest torsion, emergent surgical consultation is warranted. If the diagnosis is equivocal, adjunctive tests should be performed to determine the cause of the pain. Although urinalysis results suggestive of infection are consistent with epididymitis, such findings also may be noted in patients with torsion and a concomitant UTI.

Imaging. Ultrasound imaging for testicular torsion has a sensitivity of 64% to 100% and specificity of 97% to 100%.30,31 The torse testicle typically will be hypoechogenic and enlarged (Fig. 89.12). False-negative findings occur when the testicle is examined early in the course of the disease, when blood flow is still present, and with intermittent torsion. Examination of the spermatic cord for twisting, instead of the testicle itself, has been shown to reduce the frequency of these false-negative results.

Color Doppler techniques can improve the specificity of ultrasound imaging to 100% by demonstrating reduced blood flow to the affected testicle. Doppler studies can be more difficult to interpret in younger boys because blood flow is physiologically low in the testicles of prepubertal boys. As many as 50% of boys younger than 8 years do not show intratesticular flow.32 This hypovascularity can result in false-positive diagnoses, which could potentially lead to unnecessary surgical exploration. Comparison with the contralateral testicle can help avoid this misdiagnosis; as in normal patients, blood flow to the two testicles will be similar.

The color Doppler appearance of the testicle depends on the degree of twisting of the spermatic cord. With 180 degrees or less of twisting of the cord, venous flow from the testicle ceases but arterial flow persists. This leads to edema of the testicle on ultrasound that can be misinterpreted as inconsistent with torsion. In contrast, with more than 180 degrees of twisting of the cord, arterial flow also ceases, leading to a lack of Doppler signal on ultrasound.

Parenchymal echo texture on ultrasound may help predict the viability of the testicle. A homogenous echo texture of the parenchyma has been associated with a higher likelihood of testicular salvage. A retrospective review of 25 cases of testicular torsion has found a zero recovery rate in testes with heterogeneous echogenicity.33 In the future, the parenchymal appearance may help determine patients who are appropriate candidates for emergent surgery.

Color Doppler ultrasound imaging has the advantage of being an inexpensive and rapid test, readily performed in the ED setting. It is helpful when it demonstrates torsion in patients with equivocal findings on the history and physical examination, but it does not have sufficient sensitivity to rule out a diagnosis of torsion.
An analysis of 669 scrotal ultrasounds has revealed a 98% negative predictive value for torsion. A urologist should evaluate any patient in whom ultrasound findings are negative but history and physical findings are suggestive of torsion. Moreover, an ultrasound examination should never delay evaluation by a urologist in any patient with probable torsion.

Magnetic resonance imaging (MRI) and radionuclide scanning of the scrotum have also been used to diagnose testicular torsion but are time-consuming. They have largely been replaced by ultrasound.

Management. The first step in the management of suspected testicular torsion is immediate consultation with a urologist. The longer the spermatic cord remains twisted, the lower the likelihood of testicular salvage. In addition, early consultation allows the urologist to accompany the patient to ultrasound—if imaging is obtained—where images can be reviewed in real time with the radiologist. After consultation, IV access is established, and analgesia is provided systemically or with a block of the spermatic cord.

If the urologist is not readily available, manual detorsion should be attempted. Relief should be felt when the operator rotates the affected testicle away from the midline, as if turning the pages of a book. If this maneuver is successful, patients should report immediate improvement of symptoms. If only partial relief of pain is noticed, an attempt should be made to untwist past 360 degrees because a higher degree of rotation may be present. If pain increases or there is no relief, consider reversing the direction of reduction because up to one-third of cases can be torsed laterally. The use of ultrasound can help guide this procedure. If manual detorsion is attempted, a spermatic cord block or systemic analgesics should be administered (Fig. 89.13). In addition, evaluation by a urologist should never be delayed to perform this or any other test or maneuver.

Regardless of the outcome with manual detorsion or duration of symptoms prior to presentation, patients still require surgical evaluation. A surgeon can confirm the reduction and stabilize the testes with orchiopexy. Even for symptoms lasting beyond 24 hours, testicular salvage is possible for incomplete torsion, and orchiopexy can help prevent recurrence. Removal of a necrotic testicle speeds recovery.

Disposition. Rapid diagnosis of testicular torsion is essential and should be followed by emergent surgical scrotal exploration and bilateral orchiopexy, if necessary. Loss of the testicle is usually a result of delay in seeking medical attention. However, almost 30% of cases of failed testicular salvage have been attributed to misdiagnosis, and another 13% to a delay in treatment after the proper diagnosis was established. Misdiagnosis almost universally leads to orchietomy and represents a common source of litigation.

Torsion of Appendages of the Testis

A normal scrotum has several vestigial appendages that can also twist and become ischemic, with resultant scrotal pain. This process is most common between 7 and 14 years of age, with a mean age of 10 years. In retrospective analyses, torsion of an appendage rivals epididymo-orchitis as the most common cause of the acute scrotum.

The appendix testis, a remnant of the paramesonephric duct, is present in 92% of patients. It is located on the superior aspect of the testicle, between the testis and epididymis (Fig. 89.14). This appendage is prone to torsion owing to its pedunculated shape. After several days of ischemia from torsion, it will undergo necrosis, with eventual reabsorption. Its loss does not permanently affect fertility or have any impact on surrounding structures.

Clinical Features. As with testicular torsion, patients with torsion of an appendage complain of scrotal pain but report milder symptoms, with a more gradual onset. They report nausea, vomiting, urinary symptoms, or previous episodes of similar pain less commonly than patients with testicular torsion. They usually seek medical attention later than patients with testicular torsion, generally after 48 hours of symptoms.

On physical examination, twisting of the appendix testis leads to formation of a hard, tender, 2- to 3-mm nodule at the upper pole of the testicle. Unlike in testicular torsion, the entire testicle is not tender. The testicle also does not change in overall size, and the scrotum typically does not swell until late in the disease process. The cremasteric reflex typically is intact. On transillumination, the ischemic appendage may rarely be seen as a blue dot.

Diagnostic Testing. Urinalysis does not show evidence of infection. On ultrasound imaging, the appendix under torsion will appear hypoechoic. Color Doppler ultrasound can show decreased flow in normal and torsed appendages. With torsion of the appendix, a hypoechoic spherical nodule with a diameter more than 5 mm is present over the superior aspect of the testicle (Fig. 89.15).

Management and Disposition. If testicular torsion is ruled out, surgical excision of the appendix is rarely necessary. Treatment consists of scrotal support, ice, and NSAIDs. Resolution of symptoms can be expected within 7 to 10 days. Surgical excision is reserved for uncontrollable pain.

Epididymitis

Epididymitis is the most common intrascrotal inflammatory disease. Most cases occur in men between 18 and 35 years of age, but the disease can affect males at any age. It is uncommon in prepubertal males. If untreated, it can lead to orchitis, testicular abscess and, rarely, sepsis.

The epididymis is a tightly coiled tubular area along the posterior aspect of the testes, where sperm mature before their transit to the vas deferens. The epididymis becomes infected when organisms travel retrograde from the vas deferens. With infection, the ipsilateral testicle is also commonly involved, a condition referred to as epididymo-orchitis.

The common route of infection is local extension, mainly due to infections spreading from the urethra (sexually transmitted pathogens) or bladder (urinary pathogens). The particular organisms involved in the infection depend on the sexual activity of the patient. Although the literature classically describes men younger than 35 years who are prone to C. trachomatis and N. gonorrhoeae infections, all sexually active men, regardless of age, are at risk for epididymitis from these organisms. Acute epididymitis caused by sexually transmitted enteric organisms occurs in men who are the insertive partner during anal intercourse. Other rare causes of epididymitis include M. tuberculosis, Treponema pallidum, fungal infections, amiodarone use, and systemic inflammatory conditions such as Behçet’s syndrome.

In men older than 35 years, urinary tract pathogens become the predominant cause of epididymitis. Unlike younger patients, older men with epididymitis tend to have urinary tract abnormalities that predispose them to these infections. Over 50% of men older than 60 years with epididymitis have lower urinary tract obstruction. Older men also are more likely to have concomitant prostatitis, benign prostatic hypertrophy (BPH), immunosuppression, or systemic disease or have undergone recent genitourinary instrumentation or catheterization.

Epididymitis in children is usually idiopathic, although children can also have congenital genitourinary anomalies that predispose them to recurrent infection. The most commonly
associated abnormality is neurogenic bladder, which produces increased pressure during urination and reflux into the ejaculatory ducts. In infants, bacterial causes are more common.

Clinical Features. Patients with epididymitis experience scrotal pain of gradual onset, prompting them to present later in the clinical course than patients with torsion. Initially, this pain may reside in the lower abdomen or flank, caused by inflammation of the vas deferens. Fever is uncommon. In the early stages of the disease, tenderness is localized to the epididymis but quickly spreads to the ipsilateral testicle. Later in the course, the scrotum can become edematous, erythematous, and extremely tender. The
and should be used, when available. Studies have suggested that this diagnostic regimen is underused, with less than 10% of adults with epididymitis undergoing testing for STDs. Studies have suggested that systemic leukocytosis may be present but is a nonspecific finding and does not differentiate epididymitis from torsion. In prepubertal children, urinalysis and urine culture rarely are positive; a retrospective review of 73 children with epididymitis has demonstrated bacteriuria in only one child. Nevertheless, in these patients, urine cultures should still be obtained to rule out bacterial infection because untreated bacterial infections may lead to long-term complications.

Because the history and physical examination features and laboratory results cannot reliably distinguish torsion from epididymitis or other diseases, equivocal presentation for epididymitis versus testicular torsion should be assessed using testicular ultrasound with Doppler. On ultrasound, an inflamed epididymis appears enlarged and hypoechoic (Fig. 89.16). However, a minority of patients with torsion have preserved flow that can appear similar to that of epididymitis; in these cases, the presence of a spermatic cord twist, indicative of torsion, should be sought.

Diagnostic Testing. The diagnosis of epididymitis is typically made based on compatible physical examination findings and confirmed by laboratory testing. A urinalysis usually demonstrates evidence of pyuria. If patients are at risk for STD, a urethral swab or first-void urine sample should be tested for C. trachomatis and N. gonorrhoeae; a polymerase chain reaction (PCR) assay and other nucleic acid amplification tests have the greatest sensitivity and should be used, when available. Studies have suggested that this diagnostic regimen is underused, with less than 10% of adults with epididymitis undergoing testing for STDs. Systemic leukocytosis may be present but is a nonspecific finding and does not differentiate epididymitis from torsion. In prepubertal children, urinalysis and urine culture rarely are positive; a retrospective review of 73 children with epididymitis has demonstrated bacteriuria in only one child. Nevertheless, in these patients, urine cultures should still be obtained to rule out bacterial infection because untreated bacterial infections may lead to long-term complications.

Because the history and physical examination features and laboratory results cannot reliably distinguish torsion from epididymitis or other diseases, equivocal presentation for epididymitis versus testicular torsion should be assessed using testicular ultrasound with Doppler. On ultrasound, an inflamed epididymis appears enlarged and hypoechoic (Fig. 89.16). However, a minority of patients with torsion have preserved flow that can appear similar to that of epididymitis; in these cases, the presence of a spermatic cord twist, indicative of torsion, should be sought.

Prepubertal children with recurrent epididymitis should undergo renal ultrasound and cystography to identify potential underlying urinary tract abnormalities. These are important to identify to reduce the risk of future inflammation.

Management. Empirical antibiotics are selected in accordance with the patient’s age, sexual history, and any previous genitourinary tract abnormalities or instrumentation (Table 89.10). Treatment focuses on curing infection, improving symptoms, preventing transmission, and reducing future complications.

In patients with a suspected sexually acquired infection, ceftriaxone, 250 mg IM, should be given to treat possible N. gonorrhoeae infection. In conjunction, doxycycline, 100 mg PO bid for 10 to 14 days, should be started to treat C. trachomatis or Ureaplasma urealyticum infection. Treatment of sexual partners should be arranged, even if the partner’s culture demonstrates no growth.

In patients with infection by enteric organisms, levofloxacin, 500 mg PO once daily, or ofloxacin, 300 mg PO every 12 hours,
spread from the epididymis, frequently referred to as epididymo-
orchitis. The most frequent bacterial pathogens are \textit{N. gonorrhoae}, \textit{C. trachomatis}, \textit{E. coli}, \textit{Klebsiella}, and \textit{P. aeruginosa}. These organisms tend to infect postpubertal males and men older than 50 years with BPH.

\textbf{Clinical Features}. A patient with mumps orchitis has testicular pain and swelling that commonly begins 4 to 6 days after the onset of parotitis, although it can develop in the absence of parotitis. The clinical course varies, with adults having more severe symptoms. Clinical resolution generally occurs in 4 to 5 days.

Patients with bacterial orchitis typically have fever and scrotal pain. They often have constitutional signs and symptoms, including nausea, vomiting, myalgias, and malaise. The affected testicle—the disease is unilateral in 70% of patients—and the scrotum are swollen, tender, and erythematous.

\textbf{Diagnostic Testing}. As with all causes of scrotal pain, the first priority is to exclude testicular torsion. If the patient clearly has mumps orchitis based on the clinical presentation and a history of preceding parotitis, no other tests are necessary. For all other patients, urinalysis, urine culture, and ultrasound should be performed. On ultrasound, orchitis shows hypervascularity, commonly described as a testicular inferno. Blood tests are typically not helpful, because false-negative results are common with serologic testing, particularly in vaccinated individuals.

\textbf{Management}. In sexually active patients, ceftriaxone and doxycycline should be used to cover \textit{N. gonorrhoeae} and \textit{C. trachomatis}. In older patients, fluoroquinolones provide the best coverage of gram-negative organisms. Treatment of viral orchitis is supportive only. Although steroids may improve symptoms, they can reduce testosterone levels. All patients should receive local scrotal care as described for epididymitis. Patients with marked pain, high fever, or constitutional symptoms merit hospitalization and parenteral antibiotics.

\textbf{Testicular Tumors}

\textbf{Principles}. Tumor of the testis is the most common malignancy in young men but accounts for only 1% of all cancers in men. These tumors are more common in infertile patients and whites. They also occur with increased frequency in the non-descended and descended testicles of patients with cryptorchidism. Approximately 95% of testicular tumors are germ cell tumors, with 50% of these being seminomas and the other 50% being mixed types, including teratomas, choriocarcinomas, and yolk sac tumors. The other 5% of testicular tumors are sex cord stromal tumors. The disease course will depend on the type of tumor present, as well as the age of the patient.

\textbf{Clinical Features}. Testicular cancer usually presents as a painless, unilateral scrotal mass or as an incidental ultrasound finding. However, scrotal pain may be the first symptom in up to 20% of cases of patients with testicular cancer. Unlike other painless scrotal masses, such as hydroceles and varicoceles, tumors cannot be separated from the underlying testicle. Palpable tumors are more likely to be malignant compared with tumors identified only with imaging.

\textbf{Diagnostic Testing}. All patients with a scrotal enlargement or palpable scrotal lesions on physical examination should undergo a scrotal ultrasound examination. This study can reveal a concomitant hydrocele or homogeneous hypoechoic lesion. Intratesticular tumors are typically hypervascular, with irregular branching vessels. Leydig cell tumors are unique, because they show hypervascularity around the lesion but no internal color.

\section*{Orchitis}

Orchitis is a rare acute infection of the testes. With the exception of viral diseases, genitourinary tract infections seldom primarily involve the testes. It is most common in prepubertal boys, with viral infections such as mumps causing most cases. Orchitis rarely develops in prepubertal boys with mumps but is more common in adolescent males with mumps. It tends to arise several days after the onset of parotitis. Although vaccination has significantly reduced the incidence of mumps infection, sporadic outbreaks have occurred. Infections in vaccinated individuals are increasingly common, presumably resulting from vaccine failure or antigenic differences between the infecting and vaccine strains.

Owing to the testes’ relatively high threshold of resistance to infection, bacterial orchitis usually results from local bacterial spread from the epididymis, frequently referred to as epididymo-

\section*{Tumor of the testis is the most common malign -
Doppler flow. Although helpful for staging purposes, CT scans of the chest and abdomen are necessary in the ED only if the patient has complaints related to these parts of the body. Most paratesticular masses are benign lesions such as epididymitis, spermatoceles, hydroceles, or hernias.

**Management and Disposition.** Urgent referral to a urologist is indicated for patients with intratesticular masses. The radiosensitive nature of seminomas renders the combined treatment of orchietomy and radiation therapy highly successful for early-stage disease. Testicular cancer has become one of the most curable solid neoplasms, with an expected 5-year survival rate over 95%.

### Testicular Trauma

The most concerning injury associated with trauma involves rupture of the testicle. Testicular rupture is characterized by tear of the tunica albuginea and extrusion of the seminiferous tubules. The presentation can range from a tender, large, blood-filled scrotum to minimal swelling, with mild pain of the testicle. If there is any concern for rupture, scrotal ultrasound is indicated. Disruption in the echogenic tunica albuginea is 100% sensitive and 65% specific for rupture. Early surgical intervention is associated with higher rates of testicular salvage. Hematomas can be intratesticular or extratesticular, with or without testicular rupture. Similar to rupture, rapid evacuation of an intratesticular hematoma will reduce the risk of necrosis. Extratesticular hemorrhage into the tunica vaginalis is termed a **hematocele** and is the most common finding after blunt scrotal injury. Surgical exploration with hematoma extraction is recommended for patients with large hematomas to prevent testicular atrophy. Approximately 10% of patients with testicular torsion have associated trauma and require prompt identification and detorsion.

### Inguinal Hernia, Acute Hydrocele, Varicocele, and Spermatocele

Inguinal hernias, hydroceles, varicoceles, and spermatoceles are considerations in the differential diagnosis of an acute scrotal mass. These clinical entities are typically painless and readily identifiable on physical examination.

Most children with inguinal hernias will not have a palpable mass on examination but will report a history of intermittent bulge in the groin that appears with straining or crying. Less commonly, an inguinal mass is palpable and may extend into the scrotum. If this mass becomes incarcerated, it will be tender, and often the overlying skin will be edematous and erythematous. Children typically will develop irritability, vomiting, or abdominal distention. Incarcerated hernias should be reduced promptly to prevent bowel infarction from strangulation. Reduction can be accomplished by placing the patient in a Trendelenberg position and applying gentle pressure to expel the gas and stool in the bowel from the hernia. Pressure is then applied over the distal aspect of the hernia to reduce the bowel. If this technique fails, surgery is consulted. After reduction of an incarcerated hernia, children typically require hospitalization and delayed surgical repair.

Acute hydroceles typically are benign. They are caused by the accumulation of fluid between the two layers of the tunica vaginalis. They are painless, localized to the scrotum, and will transilluminante.

Varicoceles are enlarged spermatic cord veins that typically are painless or cause only minimal discomfort. On examination, they are often described as feeling similar to a bag of worms, just superior to the testicle, and decrease in size when the patient is supine. In contrast, a spermatocele is a sperm-containing cyst that is palpated as a nontender mass posterior to the testicle. Ultrasound is diagnostic of these conditions. No emergent treatment is necessary, but patients require outpatient urologic evaluation.

Regardless of the cause of the scrotal swelling, concomitant pathology is always a consideration. A careful evaluation for torsion, epididymitis, and tumors should be performed.

### ACUTE URINARY RETENTION

#### Epidemiology

Acute urinary retention (AUR) is the sudden inability to pass urine voluntarily from the bladder. The lifetime risk of AUR increases with age, occurring in 10% of men in their 70s and in 33% of men in their 80s. AUR is usually caused by an obstructive lesion but also can be the presenting manifestation of other pathologic processes. AUR in women is much less common than in men; common causes in women include anatomic bladder, inflammation occurring postpartum or secondary to herpes, Bartholin’s abscess, acute urethritis, or vulvovaginitis. In younger patients, it usually is caused by obstruction, cystitis, and neurologic disturbances.

#### Pathophysiology

Holding urine requires relaxation of the bladder detrusor muscle through parasympathetic inhibition and β-adrenergic stimulation and contraction of the bladder neck and internal sphincter through α-adrenergic stimulation. Conversely, micturition requires a coordinated contraction of detrusor muscle, with the simultaneous relaxation of the urethral sphincter muscle. AUR results from a disruption of this coordinated physiology caused by an increased resistance to flow via mechanical (eg, urethral stricture, clot retention) or dynamic means (eg, increased α-adrenergic activity, prostatic inflammation) or decreased neurogenic control of the detrusor muscle (eg, drugs inhibiting bladder contractility, diabetes cystopathy).

The most common cause of AUR seen in the ED is obstruction of the urinary tract distal to the bladder. In men, BPH is the most common precipitant. Enlargement of the prostate coupled with constriction of the prostatic urethra from heightened α-adrenergic tone obstructs urinary output. Strictures of the urethra after prior procedural trauma, infection, or radiation therapy can also lead to AUR. Other less common obstructive causes of AUR include prostate cancer, phimosis (inability to retract the foreskin over the glans penis) and paraphimosis (inability to reduce the foreskin over an edematous glans). In women, the most frequent obstructive causes are pelvic masses and prolapse of pelvic organs such as the bladder, rectum, or uterus. These structures cause AUR by compressing the urethra and obstructing urine flow. Finally, congenital posterior urethral valves are the most common source of AUR in children.

Infectious and inflammatory conditions can also cause AUR from urethral edema and obstruction, particularly in the setting of underlying prostatic disease. The most common infectious causative disorder is acute prostatitis, followed by urethritis and vulvovaginitis. In pediatric patients, UTIs can induce sufficient dysuria that the child refuses to void, with consequent urinary retention.

Pharmacologic agents associated with AUR include the anticholinergic and sympathomimetic agents. Anticholinergic agents inhibit detrusor muscle contraction, whereas sympathomimetic agents increase α-adrenergic tone in the prostate. NSAIDs and calcium channel blockers have also been known to increase the rate of AUR by inhibiting prostaglandin and calcium-mediated detrusor muscle contraction.
Neurogenic causes of AUR result from a cortical, spinal cord, or peripheral nerve deficit in the sensory or motor nerve supply of the detrusor muscle. Most neurologic causes of AUR are chronic conditions such as multiple sclerosis, Parkinson’s disease, neoplasms, and diabetic peripheral neuropathy. Other more acute neurologic conditions that should be diagnosed emergently as causative factors in the ED include spinal trauma, stroke, epidural plasms, and diabetic peripheral neuropathy. Other more acute conditions such as multiple sclerosis, Parkinson’s disease, neoplasm, and diabetes mellitus can lead to AUR.

Clinical Features

Although the potential causes of AUR are many, the history and physical examination can considerably narrow the scope of the differential diagnosis (Table 89.11). Most patients with AUR report sudden pain and have a distended tender bladder. Patients with dementia or limited verbal ability may only present with restlessness and agitation. With lesions proximal to the bladder, patients typically note pain in the flank, whereas lesions distal to the bladder can produce pain radiating to the scrotum or labia. With acute obstruction, pain is often quite severe. Patients with slowly developing or chronic obstructions are typically older and report overflow incontinence and little to no pain.

When obstruction is the cause of AUR, the patient often will recall multiple previous episodes of urinary retention. In addition to this history, patients with BPH report frequency, urgency, hesitancy, nocturia, difficulty initiating the urinary stream, decreased force of the stream, sensation of incomplete voiding, and terminal dribbling. The prostate is enlarged, firm, and non-nodular. Normal findings on the prostate examination do not exclude BPH. Patients with prostate cancer can have similar symptoms, but these are more often accompanied by weight loss, bone pain, and other constitutional signs and symptoms. These patients generally will have an enlarged nodular prostate. Examination of the penis is important to identify phimosis or paraphimosis. In women with obstruction, pelvic pain and pressure are symptoms commonly associated with AUR. A prolapsed bladder, rectum, or uterus and enlarged ovaries or uterus can be identified on pelvic examination.

Patients with an infectious cause for their symptoms may complain of dysuria, frequency, urgency, hematuria, fever, chills, and low back pain. In acute prostatitis, these symptoms can be associated with penile discharge and a tender boggy prostate. Despite the obstruction, the patient may nevertheless be able to void small amounts of urine. In vulvovaginitis and urethritis, presenting complaints also may include discharge, pruritus, and vulvar skin findings.

Patients with a neurogenic cause for AUR may already have a history of neurologic disease that contributes to AUR. The examination should focus on any findings suggestive of acute neurologic deficit. Strength, sensation, and reflexes in the lower extremities should be examined because they have similar innervation to that of the bladder. The status of the bulbocavernous reflex, anal reflex, sphincter tone, and perineal sensation should also be assessed.

Differential Diagnosis

The differential diagnosis for AUR is very broad and dependent on the patient’s symptoms (Box 89.6). AUR presenting as lower abdominal pain may present similarly to small bowel obstruction, urinary tract infection, or prostatitis. Flank and back pain secondary to hydronephrosis can be confused with nephrolithiasis, pyelonephritis, and spinal pathology. Urinary symptoms of overflow incontinence and urinary hesitancy can be confused with urinary tract infection or spinal cord compression. Genital pain may present similarly to trauma, testicular torsion, or inguinal hernia.

Diagnostic Testing

The only suggested diagnostic test in the ED for AUR is urinalysis. It can reveal infection or the presence of hematuria from infection, tumor, or calculi. A basic chemistry panel for the assessment of renal function should be performed only when renal damage or hydronephrosis is a concern. There is no history, physical examination, or ultrasound finding that can reliably correlate

*In the emergency department setting, each of these diagnoses is made primarily by the history and findings on the physical examination. Additional tests are needed as described.

CT, Computed tomography; MRI, magnetic resonance imaging; UA, urinalysis.
Selected Urologic Disorders

Gradual decompression has been recommended to prevent these complications. Neither has been proven to have any clinical significance. We recommend that all patients with AUR undergo rapid and complete decompression of the bladder. Although the catheter is an inconvenience for the patient, and chronic use has been associated with UTIs, trauma, stones, and urethral strictures, early removal of the catheter is also associated with heightened risk for recurrence of AUR, which has been reported in up to 70% of cases. Leaving the catheter in place for 3 to 7 days decreases the incidence of recurrent retention.

Studies have suggested that administration of an α-adrenergic blocker, such as tamsulosin, at the time of catheter insertion improves the likelihood of spontaneous voiding after catheter removal and may also improve the likelihood that a patient will not require ongoing catheter placement. These medications are associated with an increased risk of orthostatic hypotension, particularly in older adults, so initiation of treatment should be coordinated with the patient’s primary care physician.

5-Alpha-reductase inhibitors, another agent typically used for BPH, have not been shown to reduce the recurrence of AUR.

Prophylactic antibiotic therapy is not recommended for patients with AUR. Although bacteriuria often develops in patients with indwelling catheters, it typically is not clinically significant, and the use of prophylactic antibiotics only promotes resistance.

Definitive therapy often requires surgical correction of any underlying cause. Immediate placement of a 14 Fr to 18 Fr Foley catheter should provide decompression of the bladder. If this fails, placement of an elbowed catheter (coudé catheter) with a cephalad orientation should be attempted to assist bypassing by any obstruction. If both these techniques prove to be unsuccessful, urologic surgery should be consulted. If obstruction is believed to be caused by retained blood clots, a three-way catheter should be placed to allow for bladder irrigation. When immediate bladder decompression is required and a urologist is not available, major urethral trauma is present, or the patient has recently undergone urethral surgery, suprapubic bladder drainage should be performed.

Placement of a catheter has been reported to cause postobstructive diuresis, hypotension, and hematuria. Such problems are believed to be related to rapid bladder decompression so, historically, gradual decompression has been recommended to prevent these complications. Neither has been proven to have any clinical significance. We recommend that all patients with AUR undergo rapid and complete decompression of the bladder.

Additional studies are selectively indicated based on the history and physical examination to identify potentially serious or reversible causes, or when the diagnosis of AUR is unclear. With an equivocal history or physical examination, bedside ultrasound can confirm AUR. Renal and bladder ultrasound studies provide visualization of any elevated postvoid residual, obstruction, hydronephrosis, or other cause of upper urinary tract disease. Pelvic ultrasound examination and CT scan evaluate for masses or malignancy causing obstruction. MRI of the spine detects disk herniation, cord compression, and cauda equina syndrome. Cystoscopy and retrograde cystourethrography can identify problems in the lower urinary tract and usually are performed as outpatient procedures. A prostate-specific antigen assay is not helpful in diagnosing or differentiating prostate cancer from other causes of AUR and should not be routinely performed.

Management

Treatment focuses on bladder decompression and identification of the underlying cause. Immediate placement of a 14 Fr to 18 Fr Foley catheter should provide decompression of the bladder. If this fails, placement of an elbowed catheter (coudé catheter) with a cephalad orientation should be attempted to assist bypassing by any obstruction. If both these techniques prove to be unsuccessful, urologic surgery should be consulted. If obstruction is believed to be caused by retained blood clots, a three-way catheter should be placed to allow for bladder irrigation. When immediate bladder decompression is required and a urologist is not available, major urethral trauma is present, or the patient has recently undergone urethral surgery, suprapubic bladder drainage should be performed.

Placement of a catheter has been reported to cause postobstructive diuresis, hypotension, and hematuria. Such problems are believed to be related to rapid bladder decompression so, historically, gradual decompression has been recommended to prevent these complications. Neither has been proven to have any clinical significance. We recommend that all patients with AUR undergo rapid and complete decompression of the bladder.

Although the catheter is an inconvenience for the patient, and chronic use has been associated with UTIs, trauma, stones, and urethral strictures, early removal of the catheter is also associated with heightened risk for recurrence of AUR, which has been reported in up to 70% of cases. Leaving the catheter in place for 3 to 7 days decreases the incidence of recurrent retention.

Studies have suggested that administration of an α-adrenergic blocker, such as tamsulosin, at the time of catheter insertion improves the likelihood of spontaneous voiding after catheter removal and may also improve the likelihood that a patient will not require ongoing catheter placement. These medications are associated with an increased risk of orthostatic hypotension, particularly in older adults, so initiation of treatment should be coordinated with the patient’s primary care physician. 5-Alpha-reductase inhibitors, another agent typically used for BPH, have not been shown to reduce the recurrence of AUR.

Prophylactic antibiotic therapy is not recommended for patients with AUR. Although bacteriuria often develops in patients with indwelling catheters, it typically is not clinically significant, and the use of prophylactic antibiotics only promotes resistance.

Definitive therapy often requires surgical correction of any underlying cause. This should not be performed emergently because early surgery is associated with increased morbidity.

Disposition

After bladder drainage, healthy and reliable patients can be safely discharged from the ED with an indwelling catheter and urology follow-up. Patients with concomitant infection, significant comorbid illnesses, impaired renal function, neurologic deficits, or complications from catheterization require further diagnosis and treatment and probably admission.
HEMATURIA

Blood in the urine can be microscopic or gross. Although generally associated with a benign process, it can reflect serious underlying pathology, such as a urothelial malignancy. Therefore, following ED assessment, patients with hematuria require outpatient follow-up. Less commonly, patients come to the ED complaining of gross blood in their urine. Compared to microscopic hematuria, gross blood in the urine is more likely to be a presenting symptom of an underlying malignancy. Regardless of age or visibility of blood in the urine, patients with hematuria require evaluation in the ED to rule out life-threatening diagnoses, such as malignancy and AAA.

Gross and microscopic hematuria can arise from anywhere along or near the urinary tract. In the upper and lower portions of the urinary tract, infection, trauma, and renal calculi are the most common causative disorders. Patients also can have more serious causes of hematuria, such as malignancy or vascular lesions (eg, AAA), and these diagnoses should be excluded. Up to 5% of patients with asymptomatic microscopic hematuria and up to 30% to 40% of patients with gross hematuria are found to have a urinary tract malignancy. The risk of urologic malignancy is increased in patients older than 35 years, male gender, and those with a history of smoking.

Occasionally, hematuria also has been attributed to warfarin use, BPH, and exercise. Supratherapeutic anticoagulant therapy can lead to blood in the urine, but therapeutic anticoagulation does not typically produce spontaneous hematuria. Similarly, BPH can lead to increased vascularity of the prostate but does not increase the risk of hematuria. High-intensity exercise also can produce hematuria. This bleeding typically is transient and clinically inconsequential. Because warfarin use, BPH, and exercise do not directly cause persistent hematuria, patients with ongoing bleeding require further urologic evaluation.

Clinical Features

A careful history will often identify a benign cause for hematuria, such as menstruation, recent heavy exercise, recent urologic procedure, sexual activity, and the use of agents that can produce red urine without blood (Box 89.7). Repeated episodes of bleeding during and after menstruation in women suggest endometriosis of the urinary tract. Patients may report frequency, urgency, and dysuria in the setting of infection. They may note flank pain with urolithiasis or pyelonephritis. Microscopic hematuria in the setting of a UTI should resolve after appropriate antibiotic treatment.

The physical examination may point toward the underlying cause. For example, hypertension occurs with glomerulosclerosis and, in the setting of peripheral edema, suggests nephrotic syndrome. An abdominal bruit may be caused by an arteriovenous fistula, whereas a palpable abdominal mass may represent an AAA. Flank pain and tenderness can arise with pyelonephritis or nephrolithiasis. The external genital examination can show evidence of trauma or a tumor and may reveal a rectal or vaginal source for the bleeding. A pelvic examination should be performed in women to identify a vaginal or uterine source of bleeding.

Diagnostic Testing

Microscopic hematuria is defined as the presence of three or more RBCs/high-power field (hpf) of urinary sediment. A clean-catch or catheterized urine specimen should be obtained in all patients with hematuria. Catheterization itself induces hematuria in approximately 15% of patients, but the amount of bleeding is inconsequential, rarely exceeding three RBCs/hpf. Bedside urine dipstick testing of this urine should be performed. A negative urine dipstick rules out the presence of hematuria and obviates the need for urine microscopy. If positive for blood, urine microscopy should be performed.

As little as 1 mL of whole blood in 1 L of urine can produce gross hematuria, turning the urine red. A number of other substances and reactions can turn the urine red, and centrifugation of the urine and microscopic analysis differentiate these false-positive results from true hematuria. After centrifugation, the red color persists only in the urine sediment with hematuria. By contrast, a red supernatant that contains no RBCs on microscopic analysis typically represents a benign condition (see Box 89.7).

Microscopy will reveal WBCs in addition to RBCs in the presence of infection. Proteinuria, cellular casts, and dysmorphic red blood cells are seen with glomerular disease. Patients with these findings may also have cola-colored urine and should be referred to a nephrologist.

Management and Disposition

The combination of a careful history, physical examination, and laboratory studies should identify benign causes of microhematuria such as infection, menstruation, vigorous exercise, and trauma. According to the AUA Guideline on Asymptomatic Microhematuria, once benign causes have been ruled out, a prompt outpatient urologic evaluation should occur.11 This evaluation generally consists of an assessment of renal function (BUN and creatinine levels, calculated GFR) and multiphasic CT urography, including sufficient phases to evaluate the renal parenchyma and urethelium of the upper tracts. CT urography identifies hydronephrosis, urinary calculi, and renal and ureteral lesions. For patients with contraindications to contrasted CT, MR urography is an acceptable alternative imaging approach. Finally, the guidelines recommend that cystoscopy be performed on all patients aged 35 years or older or those with risk factors for urinary tract malignancy, such as tobacco use, exposure to carcinogenic chemicals (eg, aniline dye, benzidine, petroleum products), or history of chronic UTIs. Risk factors for urinary tract malignancy in patients with microscopic hematuria are listed in Box 89.8. For persistent microhematuria following a negative evaluation, yearly urinalyses are recommended, with consideration for a repeat urologic examination every 3 to 5 years.

By contrast, patients with gross hematuria require a thorough evaluation before discharge from the ED. Renal function should be assessed to rule out the development of renal insufficiency. The patient should also undergo appropriate imaging tests, although clear consensus is lacking on the appropriate radiographic study.

---

**Box 89.7**

**Causes of Red-Colored Urine Without Hematuria**

- Phenazopyridine
- Nitrofurantoin
- Rifampin
- Chloroquine
- Hydroxychloroquine
- Iodine
- Bromide
- Food coloring
- Beets
- Berries
- Rhubarb
If the initial assessment fails to identify a benign cause for the hematuria, a CT scan with contrast or renal ultrasound study should be performed. CT scanning is highly sensitive for stones, masses, and other diseases of the upper urinary tract. If contrast CT must be avoided owing to pregnancy, renal insufficiency, or history of anaphylaxis to contrast medium, ultrasound imaging is the modality of choice. Ultrasound is less sensitive than a CT scan for detecting stones, small masses, and traumatic causes of hematuria.

CT is the appropriate imaging modality for traumatic hematuria because its sensitivity and specificity exceed those of ultrasound. The exact level of hematuria that should trigger imaging is unclear, but it appears that patients without gross hematuria or evidence of coexisting abdominal or pelvic injuries are unlikely to have clinically significant injuries on CT (see Chapter 40).

**Box 89.8 Risk Factors for Urinary Tract Malignancy**

- Age > 35 yr
- Past or current cigarette smoking
- Occupational exposure (chemicals or dyes)
- Analgesic abuse
- Chronic indwelling foreign body
- Chronic urinary tract infection
- Exposure to known carcinogenic or chemotherapeutic agent
- Gross hematuria
- Irritative voiding symptoms
- Pelvic irradiation
- Urologic disorder or disease

**Key Concepts**

- Urinary obstruction should be ruled out in patients with a urinary tract infection (UTI) and those in septic shock.
- Acute, uncomplicated urinary tract infections should be treated with fosfomycin, nitrofurantoin, or trimethoprim-sulfamethoxazole.
- Fluoroquinolones are not recommended as first-line therapy for uncomplicated UTI.
- The three primary predictors of stone passage without the need for surgical intervention are calculus size, location, and degree of patient pain. The most important factor that relates to passage of a calculus though the genitourinary tract is its size (stone <5 mm has a 90% chance of passing spontaneously in 4 weeks).
- Imaging is not needed in all patients with renal colic. If the signs and symptoms are atypical, the diagnosis is in question, the patient has a solitary or transplanted kidney, or appears toxic, or high-grade obstruction is suspected, imaging should be performed.
- Acute scrotal pain should be considered a result of testicular torsion until proven otherwise.
- There is no single history or physical examination finding that accurately or reliably differentiates torsion from other causative disorders. Any patient with acute onset of scrotal pain in whom the diagnosis of torsion cannot be ruled out should undergo further diagnostic testing.
- Rapid diagnosis of testicular torsion is essential and should be followed by emergent surgical scrotal exploration and bilateral orchiopexy, if necessary. Loss of the testicle usually is a result of delay in seeking medical attention.
- Scrotal pain or swelling after trauma warrants a scrotal ultrasound to evaluate for testicular rupture or torsion.
- Sexually active males should receive ceftriaxone and doxycycline to treat epididymitis. Patients in whom enteric organisms are likely the cause of epididymitis should receive fluoroquinolones. Most cases of pediatric epididymitis are idiopathic, and antibiotics are not routinely recommended.
- Acute urinary retention (AUR) is usually caused by an obstructive lesion but also can be the presenting manifestation of other pathologic processes.
- Patients with AUR and concomitant infection, pelvic mass, or neurologic deficits warrant imaging in the ED.
- Patients with AUR should have complete drainage of the bladder performed via catheterization or, if this is not possible, by suprapubic aspiration. To improve the likelihood of future spontaneous voiding in men, an α-adrenergic blocker such as tamsulosin should be given at the time of insertion.
- Most cases of microscopic hematuria are transient and idiopathic, but also can arise with infection, trauma, and exercise.

CHAPTER 89: QUESTIONS & ANSWERS

89.1. Which of the following drugs is not an appropriate first-line choice for treatment of an uncomplicated urinary tract infection (UTI) in women?

A. All of these
B. Ciprofloxacin
C. Fosfomycin
D. Nitrofurantoin
E. Trimethoprim-sulfamethoxazole

Answer: B. According to the Infectious Disease Society of America (IDSA) practice guidelines, fluoroquinolones should not be used as first-line agents for uncomplicated UTI because of increased resistance.

89.2. Which of the following clinical scenarios is not an indication for emergent imaging of the genitourinary tract?

A. 3-year-old girl with first episode of urinary tract infection (UTI)
B. 31-year-old woman with clinical pyelonephritis and normal urinalysis (UA)
C. 34-year-old man with classic renal colic
D. Pyelonephritis and fever more than 72 hours after antibiotic initiation
E. UTI in the patient with diminishing renal function

Answer: C. Other indications for imaging include a patient with renal colic and suspicion of obstruction and a female patient with multiple complex infections.

89.3. Which of the following antibiotics should be avoided during the first trimester of pregnancy?

A. All of these
B. Ciprofloxacin
C. Levofloxacin
D. Nitrofurantoin
E. Trimethoprim-sulfamethoxazole

Answer: A. Nitrofurantoin is associated with fetal malformations when used in the first trimester. Trimethoprim-sulfamethoxazole is associated with teratogenicity. In general, fluoroquinolones should not be used during pregnancy due to developmental toxicity risks.
89.4. All of the following are acceptable antibiotic choices for the treatment of pyelonephritis accept?
A. Ceftriaxone
B. Ciprofloxacin
C. Levofloxacin
D. Nitrofurantoin
E. Trimethoprim-sulfamethoxazole
Answer: D. Nitrofurantoin does not achieve therapeutic levels in the renal parenchyma and is therefore not effective for pyelonephritis.

89.5. Which of the following differentiates testicular torsion from other causes of a painful scrotum?
A. Blunt trauma to the testicle
B. Pyuria on urinalysis
C. Nighttime presentation
D. None of the above
Answer: D. There is no single history or physical examination finding that accurately or reliably differentiates torsion from other causative disorders. Any patient with acute onset of scrotal pain in whom the diagnosis of torsion cannot be ruled out should undergo further diagnostic testing.

89.6. A testis will tend to rotate laterally to medially in most cases of torsion. To detorse in these situations, you should rotate the testis medially to laterally. If this does not produce immediate relief, you should do which of the following?
A. Assume that the testicle is already necrotic and not amenable to further reduction attempts.
B. Attempt untwisting past 360 degrees because a higher degree of rotation may be present.
C. Both A and B.
D. Reverse the direction of reduction.
Answer: D. Most testes torsed laterally to medially, but some may torse medially to laterally. If no immediate relief is obtained by rotating medially to laterally, reverse the direction of the reduction attempt.

89.7. Computed tomography should be undertaken in the patient suspected of having renal colic if which of the following is present?
A. The patient has a solitary or transplanted kidney.
B. The patient has gross hematuria.
C. The patient has had a prior history of nephrolithiasis.
D. The patient presents in severe pain.
Answer: A. Imaging is appropriate for patients who have a history of nephrolithiasis who do not improve with treatment, have a urinalysis showing infection, have a solitary or transplanted kidney, or for whom a diagnosis other than renal colic is suspected.

89.8. What is the most common cause of acute urinary retention seen in the ED?
A. Infection, inflammation
B. Obstruction
C. Medications
D. Neurogenic disorder
Answer: B. Obstruction. The most common cause of AUR seen in the ED is obstruction of the urinary tract distal to the bladder (primarily benign prostatic hypertrophy).

89.9. Acute bacterial prostatitis is diagnosed by which of the following?
A. History and examination
B. Serum studies
C. Transrectal ultrasound or CT
D. Urine gram staining and culture
E. Urethral swab
Answer: A. Acute bacterial prostatitis can be diagnosed clinically; urine gram staining and culture are recommended to guide treatment.
Selected Gynecologic Disorders

Trevor R. Pour | Carrie D. Tibbles

Many women come to the emergency department (ED) with pelvic pain or vaginal bleeding. After the possibility of pregnancy-related problems has been eliminated, the primary goal is to recognize the presence of conditions that warrant urgent intervention, such as adnexal torsion, versus those that can be managed as an outpatient, such as new postmenopausal uterine bleeding. Most patients also benefit from relief of symptoms and reassurance. This chapter specifically addresses the ED management of adnexal torsion, ovarian cysts, abnormal uterine bleeding, and the provision of emergency contraception. The general approach to vaginal bleeding is discussed in Chapter 31, complications of pregnancy are discussed in Chapter 178, and sexually transmitted disease is discussed in Chapter 88.

**OVARIAN TORSION**

**Principles**

Adnexal torsion accounts for approximately 3% of gynecologic emergencies and refers to the twisting of the ovary and fallopian tube on the axis between the utero-ovarian and infundibulopelvic ligaments. Commonly, both structures are implicated in this process. However, isolated ovarian torsion and, more rarely, isolated fallopian tube torsion may occur. In ovarian torsion, venous and lymphatic obstruction occurs initially, with subsequent congestion and edema of the ovary, progressing to ischemia and necrosis.

In addition to loss of tubal or ovarian function, torsion left untreated can progress further to hemorrhage, peritonitis, and infection. Because of the dual blood supply of the ovary from the uterine and ovarian arteries, complete arterial obstruction is rare. Ovarian torsion can occur at any age, but is most common in the reproductive years because of the regular development of a corpus luteal cyst during the menstrual cycle. Most cases of torsion in this population are associated with an enlarged ovary (>5.0 cm), either secondary to benign neoplasm or cysts, as seen in ovulation induction, hyperstimulation syndrome, or polycystic ovarian syndrome. In premenarchal patients, however, torsion frequently occurs despite normal ovarian size, thought to be secondary to the excessive mobility of the adnexa relative to older patients. Masses prone to creating adhesions, such as malignant tumors, endometriomas, or tubo-ovarian abscesses, are less likely to develop torsion than benign lesions. Torsion may be a complication of pregnancy, more likely to occur in the first and early second trimesters. A history of tubal ligation is a risk factor for ovarian torsion. A slight predominance of torsion on the right side has been noted, likely related to the stabilizing effect of the fixed sigmoid colon on the left.

**Clinical Features**

The classic symptoms of ovarian torsion are severe, sharp, unilateral lower abdominal pain and nausea; however, some or all of these symptoms are often absent. Despite advances in imaging modalities, the preoperative diagnosis rate only approaches 40%, making clinical assessment more valuable. The presence of known risk factors, such as an ovarian mass or recent infertility treatments, may suggest the diagnosis in postmenarchal patients. Patients typically report pain lasting from several hours to days. Rarely, patients report pain for weeks to months in duration, most likely due to intermittent torsion. Nausea and vomiting are present in about 70% of cases.

Most patients will have unilateral tenderness on abdominal palpation, but up to 75% of patients will not have a palpable adnexal mass. Clinical decision tools for ovarian torsion have been developed but suffer from poor sensitivity and therefore cannot be recommended. Clinical signs of isolated tubal torsion are indistinguishable from those of ovarian torsion.

**Differential Diagnosis**

Considerations in the differential diagnosis include other causes of acute lower abdominal pain, such as appendicitis, ruptured ovarian cyst, urinary tract infection, nephrolithiasis, pelvic inflammatory disease, uterine leiomyoma, diverticulitis, bowel obstruction, and ectopic pregnancy. A pregnancy test, physical examination, and imaging with ultrasound or computed tomography (CT), if necessary, can usually distinguish among these possibilities.

**Diagnostic Testing**

**Laboratory Tests**

No specific laboratory tests are routinely used in the diagnosis of suspected torsion. Two small studies on serum interleukin-6, a proinflammatory cytokine, have revealed a pooled sensitivity of 85% and specificity of 84% for torsion and may evolve into a useful serum marker if reproduced by larger trials. A negative pregnancy test may exclude ectopic pregnancy from the differential, but a positive test does not rule out adnexal torsion. Leukocytosis is not a reliable indicator of torsion.

**Imaging**

**Ultrasonography.** An ultrasound examination is the initial imaging test in the evaluation of patients with pelvic pain suggestive of ovarian torsion, but findings can vary depending on timing and duration of symptoms. Asymmetric enlargement of the ovary is the most common finding. Enlargement of an ovary with a heterogeneous stroma secondary to edema along with small, peripherally displaced follicles is the classic ultrasound appearance of torsion but is often absent, particularly with long-standing ischemia. Ultrasound may reveal a mass in the ovary, evidence of hemorrhage, or free pelvic fluid (Fig. 90.2). Hemorrhagic cysts and other nonneoplastic masses frequently are associated with torsion; these may appear fluid-filled, exhibit a complex pattern with debris and septations, or be visualized as a solid mass. The characteristic appearance of torsion may be difficult to appreciate if the ovary is obscured by an associated mass. In isolated tubal
Computed Tomography. When alternative abdominal pathologies are strong considerations in the differential diagnosis for acute pelvic pain, abdominopelvic CT may be the best initial study, particularly in patients who have a presentation atypical for torsion. In ovarian torsion, CT findings include asymmetric ovarian enlargement or asymmetric adnexal enhancement following IV contrast, fallopian tube thickening, or twisted vascular pedicle, fat stranding surrounding the affected adnexa, and uterine deviation to the twisted side. Pelvic free fluid in patients with a hemorrhagic infarction can be seen. A retrospective review of CT scans of patients with confirmed torsion has found that every CT scan had evidence of an ovarian abnormality, including enlargement or the presence of a mass, suggesting that torsion is unlikely if the CT visualized a normal ovary; another, more recent case-controlled study comparing pelvic ultrasound to CT has confirmed these findings. Therefore, negative imaging findings should be interpreted with caution when clinical suspicion is high but, with lower suspicion, a normal-appearing ovary on the CT scan can be reassuring.

Magnetic Resonance Imaging. Magnetic resonance imaging (MRI) may demonstrate findings consistent with torsion. It is particularly helpful if the diagnosis is not clear, such as with intermittent pain over days, or for pregnant patients when the history is highly suggestive but ultrasound findings are inconclusive or equivocal. Findings on MRI suggestive of torsion are similar to those on CT (Box 90.1).

Laparoscopy. A diagnostic laparoscopy is the gold standard investigative modality in patients in whom clinical suspicion is high, despite negative imaging results. In one study of 100 nonpregnant patients with an acute abdomen, only 29 of the 66 laparoscopically proven cases of ovarian torsion were diagnosed preoperatively. Laparoscopy also allowed diagnosis of other unsuspected conditions, including ovarian cysts, appendicitis, and pelvic inflammatory disease.

Management and Disposition

Once the diagnosis of ovarian torsion has been made, the patient should be taken to the operating room as soon as possible. The ovary often will recover, even if black or dusky in appearance at the time of surgery, because of its dual blood supply, so attempts at ovarian salvage are warranted, even if the diagnosis is made late. This is particularly true in adolescent patients. Ovarian function returns in most patients.

torsion, tubal lesions such as hydrocelepinx or a tubo-ovarian abscess may be seen.

Doppler ultrasound findings are inconsistent for diagnosing ovarian torsion. Up to 60% of surgically proven torsion will have documented blood flow on Doppler examination (Fig. 90.3). Findings may vary depending on the time of the examination because torsion may occur intermittently, and clinical symptoms may precede arterial compromise. If a large mass is present, the examination may also be technically difficult to perform. Despite these limitations, the Doppler examination is still useful, and detection of abnormal venous flow is particularly important in early cases of torsion (Fig. 90.4). Absence of arterial flow is highly specific for torsion, with a positive predictive value of 94% to 100%. Visualization of the twisting of the pedicle and coiled vessels is referred to as a whirlpool sign and has a 90% positive predictive value for torsion.12
OVARIAN CYSTS AND MASSES

Principles

Cysts are the most common cause of gynecologic masses. They occur at any stage of life but are most frequent in the reproductive years because of the cyclic changes of the ovary associated with menstruation (Fig. 90.5). Most ovarian cysts in premenopausal and postmenopausal women are benign and resolve with no intervention, but on occasion they may be malignant or associated with complications such as hemorrhage or torsion. Benign cysts are less common in premenarchal girls, however, with an incidence of malignancy as high as 25% when an adnexal mass is found.

The most common type of cyst is a simple follicular, or functional cyst, developing from a follicle that fails to rupture or regress, and is defined as pathologic when the diameter exceeds 3.0 cm. Follicular cysts are typically thin-walled and filled with clear fluid, whereas a corpus luteal cyst is often filled with hemorrhagic fluid. Several other types of cystic masses can occur in the ovary, including endometriomas (chocolate cysts), nonneoplastic lesions such as benign cystic teratoma (dermoid cyst), fibroma, cystadenoma, and various types of malignant neoplasms.

Clinical Features

The most common presentation for patients with an ovarian cyst is pelvic pain. Rupture of a follicular cyst may produce transient...
pelvic pain, be associated with dyspareunia, or be asymptomatic. Because of its thin fragile wall, a follicular cyst may rupture during sexual intercourse or during the pelvic examination. Follicular cysts are rarely associated with hemorrhage.

Presentation of a corpus luteal cyst may range from an asymptomatic mass to dull, chronic pelvic pain to severe pain associated with rupture. Rupture of a corpus luteal cyst is frequently associated with a significant degree of hemorrhage. As with a follicular cyst, rupture may follow a pelvic examination, sexual intercourse, exercise, or trauma. Rupture of a large or complex cyst may result in severe pain and peritoneal signs. Occasionally, a large cyst may be discovered on a routine pelvic examination as an asymptomatic mass, but this is uncommon.

Differential Diagnosis

Diagnostic considerations in the patient with ovarian cysts and masses include other causes of pelvic pain that require urgent intervention, such as ectopic pregnancy, pelvic inflammatory disease, urinary tract infections, nephrolithiasis, appendicitis, and diverticulitis. Tumors or abscesses of the gastrointestinal tract may also mimic adnexal masses.

Diagnostic Testing

Laboratory Tests

The initial step in the evaluation of pelvic pain or a pelvic mass is to exclude pregnancy with a urine or serum β-human chorionic gonadotropin (β-hCG) test. A hematocrit may be valuable in the unstable patient as a marker of blood loss. The serum antigen CA-125 is elevated in 80% of women with epithelial ovarian cancer but can also be elevated by nonmalignant conditions such as endometriosis, pregnancy, and pelvic inflammatory disorder, limiting its usefulness in the emergency setting.\(^\text{19}\)

Imaging

**Ultrasoundography.** Ultrasoundography is the standard initial imaging modality used to diagnose and characterize all ovarian pathologic processes and lesions, including cysts and masses. Approximately 90% of adnexal masses are adequately characterized by ultrasound imaging alone.\(^\text{20}\) Transabdominal and endovaginal examinations provide useful information. The transabdominal approach should be performed with a full bladder as a sonographic window. It permits an overall view of the pelvis and will visualize large masses and pelvic free fluid. Use of the endovaginal probe, which should be performed with an empty bladder to reduce artifact, provides a detailed picture of the ovary. Follicles are part of the normal architecture of the ovary and are typically smaller than 1.0 cm in diameter, whereas the dominant follicle may measure up to 2.5 cm at the time of ovulation. Depending on the timing of the scan and degree of clot formation and lysis, hemorrhage may be seen. [Fig. 90.6](#) demonstrates a normal ovary with a dominant follicle ([arrows]). [Fig. 90.7](#) demonstrates a large cyst, and [Fig. 90.8](#) demonstrates hemorrhage and free pelvic fluid. Ultrasound findings suggestive of malignancy include internal...
Computed Tomography. When the differential diagnosis of unilateral pelvic pain is broad, particularly in the patient with symptoms or physical findings not solely confined to the pelvis, a CT scan may be a more appropriate initial imaging study. It is not recommended as the first-line imaging study if an adnexal mass is of primary concern due to poor soft tissue discrimination.21 Once the diagnosis of malignancy has been made, however, ultrasound is insensitive for staging or follow-up imaging, and contrast-enhanced CT is indicated at that time. A CT scan can detect a cyst and associated complications, including torsion, as noted earlier. CT findings suggestive of malignancy are a cystic solid mass, necrosis in a solid lesion, complex or cystic lesion with thick, irregular walls, and the presence of ascites, peritoneal metastases, and lymphadenopathy.

Magnetic Resonance Imaging. MRI provides better soft tissue contrast as compared with CT and has been shown in multiple studies to differentiate benign from malignant adnexal masses better as compared with ultrasound. It is limited by availability, cost, and duration of examination. MRI should be considered for pregnant patients or those with equivocal findings on ultrasound or CT.

Management and Disposition

Patients with a simple cyst and improvement in symptoms may be safely discharged with referral for outpatient gynecologic follow-up to ensure resolution of the cyst. Most uncomplicated simple cysts will resolve without further intervention. Pain should be controlled with nonsteroidal antiinflammatory drugs (NSAIDs) as a first-line approach and with oral opioids reserved only for severe cases. Oral contraceptives are not recommended for the routine management of ovarian cysts; despite being theorized to accelerate the regression of ovarian cysts, multiple randomized controlled trials have shown no difference in cyst resolution when compared to expectant management.22

A complex cyst concerning for malignancy requires more urgent gynecologic intervention. Such patients may benefit from gynecologic consultation in the ED, particularly if reliable follow-up is unlikely or if the patient is particularly symptomatic.

ABNORMAL UTERINE BLEEDING IN THE NONPREGNANT PATIENT

Principles

An understanding of the normal menstrual cycle is needed to understand the potential causes of abnormal uterine bleeding (Fig 90.9). The menstrual cycle starts on the first day of menses. During the first part of the menstrual cycle, the endometrium thickens under the influence of estrogen, and a dominant follicle develops in the ovary, releasing an ovum at the midpoint of the cycle. After ovulation, the luteal phase begins and is characterized by the production of progesterone from the corpus luteum. Progesterone matures the lining of the uterus and, if implantation does not occur, the corpus luteum dies, accompanied by sharp drops in progesterone and estrogen levels. These changes typically are followed by menstruation. Menstrual bleeding is usually predictable, cyclic, and results from withdrawal of the effects of hormones on the endometrium, which occurs approximately 14 days after ovulation.

A revised system of terminology, PALM-COEIN, regarding abnormal uterine bleeding (AUB) was created in 2011 by the International Federation of Gynecology and Obstetrics (FIGO) to...
standardize language and facilitate multiinstitutional investigation (Box 90.2). The first four letters, PALM, represent structural causes for AUB—polyp, adenomyosis, leiomyoma, and malignancy or hyperplasia, whereas the last five letters, COEIN, represent nonstructural causes—coagulopathy, ovulatory dysfunction, endometrial,iatrogenic, and not yet classified. The term dysfunctional uterine bleeding is no longer used. Disruption of the hypothalamic-pituitary-ovarian axis from a variety of causes can result in bleeding related to ovulatory dysfunction (AUB-O). Returning the balance of estrogen and progesterone with oral contraceptives will help many patients regulate the cycle, with reduction in or cessation of abnormal uterine bleeding.

Clinical Features

History

A large number of conditions cause abnormal uterine bleeding, and a systematic history and physical examination can help narrow the possibilities. Vaginal bleeding before the age of menarche is abnormal and may be the result of infection, trauma, such as sexual abuse or a foreign body, or a structural lesion. In a woman of reproductive age, abnormal uterine bleeding includes a change in the frequency, duration or amount of bleeding, or bleeding between menstrual cycles. In the postmenopausal woman, any bleeding 12 months after the cessation of menses or unpredictable bleeding during hormone therapy is abnormal. The amount and frequency of bleeding and the duration of symptoms, as well as the relationship to the menstrual cycle, should be established. A menstrual cycle shorter than 21 days in duration or more than 35 days apart, or flow for less than 2 or more than 7 days, is classified as abnormal. A pattern of irregular bleeding between cycles or an abrupt change in the previous pattern of bleeding should also be determined.

Systemic conditions, such as liver or thyroid disease, may be associated with abnormal uterine bleeding. Endometrial cancer is associated with underlying diabetes mellitus, metabolic syndrome and obesity, anovulatory cycles, nulliparity, and age older than 55 years. Cervical dysplasia or other genital tract pathology may cause postcoital or irregular bleeding, and patients should be questioned on risk factors for sexually transmitted infections. Prior history of cesarean section may contribute to iatrogenic AUB; studies have found that irregular scarring postoperatively leads to a higher prevalence of vaginal spotting. Disruption along the hypothalamus-pituitary-ovarian pathway leading to anovulation is frequently the cause of AUB. Disruption of this pathway may be physiologic, such as during adolescence, premenopause, or lactation. Pathologic causes include polycystic ovary syndrome (PCOS), hypothalamic dysfunction seen in anorexia nervosa, hyperprolactinemia, and primary pituitary disease.

Patients should be questioned about excessive bleeding or bruising or any family history of bleeding disorders because up to 20% of women presenting with heavy menstrual bleeding will have an underlying coagulopathy. Von Willebrand disease is the most common of these, seen in up to 13% of cases of AUB, and often first presents with heavy uterine bleeding since menarche.

Physical Examination

With prolonged heavy bleeding, signs of chronic anemia may be noted on the physical examination. PCOS is a common cause of abnormal uterine bleeding, and physical findings suggestive of such include obesity, acne, hirsutism, and acanthosis nigricans. Other causes of bleeding include vaginal or cervical lesions, which may be visible on the speculum examination. A leiomyoma or fibroid uterus may be palpable on the bimanual examination.

Differential Diagnosis

The cause of abnormal uterine bleeding in the nonpregnant patient is extensive but may be narrowed by age. In adolescents, consider undiagnosed coagulopathy, pelvic infection, or
Diagnostic Strategies
Laboratory Studies
In evaluating a woman of reproductive age with vaginal bleeding, a urine or serum pregnancy test is the most essential laboratory test. In a patient with excessive bleeding, hemodynamic instability, or clinical evidence of anemia (e.g., excessive fatigue, pale conjunctiva), a hemoglobin or hematocrit test may be helpful. If coagulopathy is suspected, platelet count, prothrombin and partial thromboplastin time should be measured. *Chlamydia trachomatis* testing is indicated in patients at risk of infection. Thyroid dysfunction, particularly hypothyroidism, is associated with AUB, and therefore screening to determine the thyroid-stimulating hormone serum level is recommended.

Imaging
The decision to perform ultrasound imaging in the ED depends on the urgency to determine the cause of bleeding and on the reliability of outpatient follow-up. Transvaginal ultrasonography (TVUS) may reveal a fibroid uterus, endometrial thickening, or a focal mass (Fig. 90.10). In postmenopausal patients with AUB, an endometrium measuring less than 4 to 5 mm thick on TVUS reliably excludes endometrial cancer. A thickened endometrium may indicate an underlying lesion or excess estrogen.

For most nonpregnant patients with AUB, ultrasound findings do not immediately affect ED decision making. In patients who have access to gynecologic services, imaging may be deferred until follow-up evaluation with the gynecologist.

Management
The likely causative disorder, as well as the amount of bleeding and stability of the patient, will guide ED management. NSAIDs are generally effective for relief of associated cramping pelvic pain. For anovulatory bleeding, combination oral contraceptive pills can help regulate the cycle and also counteract the long-term effects of unopposed estrogen on the endometrium. We recommend a combination oral contraceptive with 35 µg of ethinyl estradiol or 20 mg of medroxyprogesterone tid for 1 week. Contraindications must be reviewed with the patient prior to prescribing these medications, specifically to determine a history of deep vein thrombosis or pulmonary embolus, cigarette smoking, breast cancer, or liver disease.

Oral tranexamic acid, a prothrombotic agent, may also be used for outpatient management of bleeding. The dose is 1.3 g orally every 8 hours for 5 days. Rarely, a patient will have uncontrolled bleeding and signs of blood loss on presentation, in which case they should receive resuscitation with blood products, as is done for other types of hemorrhagic shock. In these patients, surgical options should be considered, including urgent dilation and curettage, uterine artery embolization, or hysterectomy. Alternatively, intravenous conjugated equine estrogen may be used and was shown in one randomized controlled trial to stop bleeding in 72% of study participants in 8 hours compared to 38% treated with placebo. The dose is 25 mg intravenously every 4 to 6 hours for 24 hours or until the bleeding stops.

Disposition
Most patients with pelvic pain from ovarian cysts or abnormal uterine bleeding without hemodynamic compromise may be managed with specific therapies to minimize symptoms and should be referred to a gynecologist for definitive management on an outpatient basis. Patients with severe, acute abnormal uterine bleeding and hemodynamic instability require urgent gynecologic consultation and hospitalization.

**EMERGENCY CONTRACEPTION**

Emergency contraception, also commonly known as the morning after pill, consists of therapy to prevent pregnancy after unprotected or inadequately protected sexual intercourse. At present, there are three oral formulations available globally—ulipristal acetate, a progesterone receptor modulator, levonorgestrel, and combined oral contraceptives consisting of progestin and estrogen.

The most commonly used regimen, and the only formulation available without a prescription in the United States, consists of a single dose of 1.5 mg or two doses of 0.75 mg levonorgestrel spaced 12 hours apart. The one-time dose is simpler to use and is at least as effective as the two-dose regimen. It is labeled for use for up to 72 hours from intercourse. Another regimen, a single tablet of 30 mg of ulipristal acetate, is only available with a prescription and has demonstrated effectiveness for up to 120 hours from intercourse, making it a preferred choice over levonorgestrel beyond the 72-hour window. Both forms of contraception are maximally effective when used within 24 hours. Combined oral contraceptives, also known as the Yuzpe method, has largely fallen out of favor due to the simplicity and success of levonorgestrel.

Adverse effects of oral emergency contraception include nausea and headache, with combined oral contraceptives producing significantly higher rates of nausea than levonorgestrel or ulipristal alone. Irregular menstrual bleeding, which can occur within 1 week to 1 month after treatment, resolves without intervention.

In addition to oral emergency contraception, the copper intrauterine device (IUD) is highly effective when placed within 5 days.
emergency contraception has not been shown to have any adverse effects on a developing fetus when taken during an established pregnancy. It is still possible for a patient who uses emergency contraception to get pregnant in the same menstrual cycle, so she should be advised to use an alternative form of contraception and to undergo a pregnancy test if menstruation is delayed for more than 3 weeks. Patients who receive emergency contraception should be counseled regarding birth control and have a follow-up pregnancy test should they miss their next period.

Both levonorgestrel and ulipristal act to delay or inhibit ovulation, whereas whereas the copper IUD prevents fertilization. As such, a common misconception is that emergency contraception is equivalent to medical abortion. None of the methods discussed involve the termination of a preexisting pregnancy, and

KEY CONCEPTS

- Ovarian torsion is easily missed on initial presentation, and diagnosis cannot rely on radiologic findings alone. Doppler ultrasound is the optimal imaging study; absence of arterial flow, although not always present, is highly specific for torsion. Torsion should be a consideration in any patient with known risk factors, even if symptoms are subtle or atypical.
- An ultrasound examination may distinguish among the various types of ovarian cysts and identify associated complications, such as torsion, hemorrhage, and malignancy. Most ovarian cysts are simple follicular cysts that resolve without pharmacologic or surgical intervention.
- Abnormal uterine bleeding has many structural, hormonal, and coagulopathic causes. Selected imaging and laboratory testing, based on a careful history and physical examination, can often lead to determination of the cause. Combined oral contraceptive pills can help regulate the cycle and alleviate AUB.
- Emergency contraception is a safe effective option to prevent an undesired pregnancy. Levonorgestrel and ulipristal are both effective oral medications and are associated with fewer side effects than the traditional combined contraceptive method.

CHAPTER 90: QUESTIONS & ANSWERS

90.1. Which of the following statements regarding ovarian torsion is true?
A. Abdominal tenderness is predictable.
B. Complete arterial obstruction is common.
C. Computed tomography (CT) has a higher sensitivity than ultrasonography.
D. Most cases are associated with an ovarian mass.
E. There is a left-sided predominance.

Answer: D. Most cases are associated with a benign ovarian tumor or cyst. There is a modest right-sided predominance. Due to the collateral uterine and ovarian arterial supply, complete arterial obstruction is rare. In cases of intermittent or chronic torsion particularly, abdominal tenderness may be absent. CT has a lower sensitivity than ultrasound, which is still only approximately 71%. Interpret negative studies carefully.

90.2. Which of the following patterns of menses should be considered abnormal?
A. A 23-day menstrual cycle
B. A 40-day menstrual cycle
C. Bleeding 6 months after menopause
D. Seven days of menstrual flow
E. Three days of menstrual flow

Answer: B. A menstrual cycle shorter than 21 days or more than 35 days apart, or flow that is less than 2 days or more than 7 days, is considered abnormal. In the postmenopausal woman, any bleeding 12 months after cessation of menses is considered abnormal.

90.3. A 33-year-old G3P3 woman presents with 7 days of heavy but painless vaginal bleeding. Her only other complaint is dizziness. Urine pregnancy test is negative. Vital signs are blood pressure, 85/40 mm Hg, and heart rate, 130 beats/min. The pelvic examination reveals copious vaginal bleeding through a partially open cervical os. The hemoglobin level is 6.8 g/dL. Which of the following is the most appropriate intervention?
A. 20 μg of ethinyl estradiol daily until the bleeding subsides
B. 35 μg ethinyl estradiol bid until the bleeding subsides
C. Blood transfusion and urgent gynecologic consultation for dilation and curettage
D. Premarin, 25 mg IV every 6 hours
E. Saline hydration followed by a 2-day recheck

Answer: C. This patient is symptomatic, hypovolemic, anemic, and exhibiting ongoing bleeding. Oral estrogens are indicated in cases of modest bleeding. Parenteral estrogen may be used as an adjunct to other therapies for patients requiring admission. The degree of anemia in the face of ongoing bleeding in this case warrants gynecologic intervention.

90.4. To be most effective, the emergency contraceptive ulipristal should be given as soon as possible but is approved to be given within how many hours of intercourse?
A. 12
B. 24
Answer: E. The efficacy of all emergency contraceptive pills in preventing pregnancy is greatest when a contraceptive is taken soon after intercourse. Ulipristal is labeled for 120 hours post-coitus. Because it is not as effective as preplanned contraception, women should still be aware of the possibility of pregnancy after its use.
**Background**

Stroke is the fifth leading cause of death in the United States and a leading cause of long-term disability. It affects about 795,000 people per year. On average, someone has a stroke every 40 seconds, and someone dies of a stroke every 4 minutes. Stroke patients have an in-hospital mortality rate of 5% to 10% for ischemic stroke and 40% to 60% for intracerebral hemorrhage (ICH). Only 10% of stroke survivors will recover completely, making stroke a leading cause of adult disability.

**Stroke** can be defined as any vascular injury that reduces cerebral blood flow (CBF) to a specific region of the brain, retina, or spinal cord, causing neurologic impairment. The onset of symptoms may be sudden or stuttering, often with transient or permanent loss of neurologic function. Approximately 87% of all strokes are ischemic in origin, caused by the occlusion of a cerebral vessel. Approximately 13% are hemorrhagic strokes caused by the rupture of a blood vessel into the parenchyma of the brain (ICH) or into the subarachnoid space (subarachnoid hemorrhage [SAH]). Only ischemic stroke involving the brain and ICH are discussed in this chapter. SAH is discussed in Chapter 93.

Prior to the reperfusion era, treatment for stroke was not focused on reversal of damage and consisted of stabilization, observation, and rehabilitation. Current acute interventional treatment regimens are designed to reverse or minimize brain damage. Strategies include blood pressure (BP) management, anticoagulation, thrombolytic therapy, catheter-based interventions, and surgery.

**Epidemiology**

Ischemic Stroke

An estimated 610,000 “first-ever” ischemic strokes occur each year in the United States. These may result from either in situ thrombosis or embolic obstruction from a more proximal source, usually the heart. In more than one-third of these first-ever strokes, no clear cause is identified. Strokes of all subtypes are more common in African American and Hispanics versus non-Hispanic whites.

Approximately one-third of all ischemic strokes are thrombotic in nature. These can be caused by either large- or small-vessel occlusions. Common areas for large-vessel occlusions are cerebral vessel branch points, especially in the distribution of the internal carotid artery. Thrombosis usually results from clot formation in the area of an ulcerated atherosclerotic plaque that forms in the area of turbulent blood flow, such as a vessel bifurcation. A marked reduction in flow results when the stenosis occludes more than 90% of the blood vessel diameter. With further ulceration and thrombosis, platelets adhere to the region. A clot then either embolizes or occludes the artery.

Lacunae, or small-vessel strokes, involve small terminal sections of the vasculature and more commonly occur in patients with diabetes and hypertension. A history of hypertension is present in 80% to 90% of patients who experience lacunar strokes. The subcortical areas of the cerebrum and brainstem often are involved. The infarcts range in size from a few millimeters to 2 cm and are seen most commonly in the basal ganglia, thalamus, pons, and internal capsule. They may be caused by small emboli or by a process termed lipohyalinosis, which occurs in patients with hypertensive cerebral vasculopathy.

One-fourth of all ischemic strokes are cardioembolic in nature. Embolization of a mural thrombus in patients with atrial fibrillation is the most common mechanism, and patients with atrial fibrillation have an approximate fivefold increased risk for development of a stroke. Noncardiac sources of emboli may include diseased portions of extracranial arteries, resulting in an artery-to-artery embolus. One common example is amaurosis fugax, in which emboli from a proximal carotid artery plaque embolizes to the ophthalmic artery, causing transient monocular blindness.

Although stroke risk increases with age, approximately 3% to 4% of all strokes occur in patients 15 to 45 years old, and there have been trends observed showing the average age of first stroke is becoming younger. Although atherosclerosis is the most common cause in elders, causative disorders and conditions in younger patients often are uncommon and may be reversible. Pregnancy, the use of oral contraceptives, antiphospholipid antibodies (such as, lupus anticoagulant and antiphospholipid antibodies), protein S and C deficiencies, sickle cell anemia, and polycythemia all predispose patients to sludging or thrombosis, thereby increasing the risk of stroke. Fibromuscular dysplasia of the cerebral vasculature also may lead to stroke, and in rare instances prolonged vasoconstriction from a migraine syndrome causes stroke. Recreational drugs such as cocaine, phenylpropanolamine, and amphetamines are potent vasoconstrictors that have been associated with both ischemic and hemorrhagic stroke. Infectious processes, particularly varicella and recently fungal meningitis, can induce vasculopathies that lead to stroke as well or can induce longer-term inflammatory processes that ultimately cause a clinical stroke.

Carotid and vertebral dissections often are associated with trauma but may follow mild events such as sneezing. Dissections are the leading determined cause of stroke in the young and are slightly less common than idiopathic strokes. Carotid and vertebral dissections also are seen more frequently in people with underlying pathology of the vessel wall, such as in fibromuscular
dysplasia and connective tissue disorders. Alteration in the vessel intima can lead to vessel stenosis, occlusion, or embolism. The patient may report a minor preceding event, such as spinal manipulation, yoga, working overhead, coughing, or vomiting. Presenting manifestations may include headache, facial pain, visual changes, cranial nerve (CN) palsies, pain over the affected vessel, Horner’s syndrome, amaurosis fugax, SAH, or an ischemic stroke. The headache frequently is unilateral and may occur days before onset of the other neurologic symptoms. Dissections are typically diagnosed by noninvasive modalities, such as ultrasonography, magnetic resonance angiography (MRA), and computed tomography angiography (CTA). Medical therapy options include early anticoagulation if SAH/intracranial dissection is not suspected. The existing data comparing antiplatelet treatment to anticoagulation is generally limited and antiplatelet treatment is generally simpler and safer. The use of tissue plasminogen activator (tPA) is considered as a safe and effective in extracranial carotid or vertebral dissection patients as in any other eligible patient.

**Transient Ischemic Attack**

A transient ischemic attack (TIA) was historically defined as a neurologic deficit with complete resolution within 24 hours; however, a portion of TIA cases have evidence of permanent brain ischemia on neuroimaging. Therefore, the American Heart Association (AHA) has adopted a tissue-based definition: A transient episode of neurologic dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction.

About 240,000 TIs per year occur in the United States, with an incidence rate of 8 per 1000 person years. TIAs constitute an important warning sign for the future development of cerebral infarction. Approximately 10% of the patients who experience a TIA will experience a stroke within 3 months of the sentinel event, and one-half of these occur within the first 2 days.

**Hemorrhagic Stroke**

Spontaneous ICH causes 10% to 15% of all acute strokes, affecting approximately 65,000 patients per year. It carries a 30-day mortality rate of up to 50% with one-half of patients dying in the first 2 days. Among survivors, only one in five are living independently at 6 months.

The two major underlying causes of ICH are hypertensive vasculopathy (caused by long-standing hypertension) and cerebral amyloid angiopathy (usually found in elders, which is the result of amyloid deposition in cerebral vessel walls). Hypertensive hemorrhage results from degenerative changes in the small penetrating arteries and arterioles, leading to lipohyalinosis of small, deep penetrating arteries. Such hemorrhages generally occur in the deep regions, including basal ganglia and thalamus. The most common sites for hypertensive hemorrhage are listed in **Box 91.1**. ICH caused by amyloid angiopathy tends to be lobar in nature and to occur more commonly in older adults.

Other factors leading to ICH include underlying vascular malformations (ie, arteriovenous malformations [AVMs] and aneurysms, drug intoxication [particularly sympathomimetics, such as cocaine], malignant hypertension, saccular aneurysms, blood dyscrasias, venous sinus thrombosis, hemorrhagic transformation of an ischemic stroke, moyamoya disease, and tumors). High-risk features for such secondary forms of ICH include lobar location, presence of intraventricular blood, and younger age.

**Pathophysiology**

The cerebral vasculature supplies the brain with a rich flow of blood that contains the critical supply of oxygen and glucose necessary for normal brain function. When a stroke occurs, there are immediate alterations in CBF and extensive changes in cellular homeostasis. The normal CBF is approximately 40 to 60 mL/100 g of brain per minute. When CBF drops below 15 to 18 mL/100 g of brain per minute, several physiologic changes occur. The brain loses electrical activity, becoming electrically “silent,” although neuronal membrane integrity and function remain intact. Clinically, the areas of the brain maintaining electrical silence manifest a neurologic deficit, even though the brain cells are viable. When CBF is below 10 mL/100 g of brain per minute, membrane failure occurs, with a subsequent increase in the extracellular potassium and intracellular calcium and eventual cell death.

The ischemic penumbra is the area of the brain surrounding the primary injury, which is preserved by a tenuous supply of blood from collateral vessels. This border zone of neuronal tissue is the area of greatest interest to investigators for possible salvage in both ischemic and hemorrhagic stroke. In ischemic stroke, the duration of occlusion plays a critical role in neuronal survival.

In ICH, acute vessel rupture is most often caused by underlying small vessel disease and causes injury by several mechanisms. First, there is mass effect from the hematoma itself, followed by activation of the coagulation cascade, release of inflammatory cytokines, and blood-brain barrier (BBB) disruption. This leads to perihematomal edema formation and secondary brain injury. Finally, continued bleeding, or hematoma expansion, occurs in many patients—either continued bleeding from the primary source, or secondary bleeding at the periphery of the hemorrhage.

**Anatomy and Physiology**

Blood is supplied to the brain by the anterior and posterior circulations. The anterior circulation originates from the carotid system and perfuses 80% of the brain, including the optic nerve, retina, and frontoparietal and anterior-temporal lobes. The first branch off the internal carotid artery is the ophthalmic artery, which supplies the optic nerve and retina. As a result, the sudden onset of painless monocular blindness (amaurosis fugax) identifies the stroke as involving the anterior circulation (specifically the ipsilateral carotid artery) at or below the level of the ophthalmic artery. The internal carotid arteries terminate by branching into the anterior and middle cerebral arteries at the circle of Willis.

The anterior cerebral artery supplies the basal and medial aspects of the cerebral hemispheres and extends to the anterior two-thirds of the parietal lobe. The middle cerebral artery feeds...
the lenticulostriate branches that supply the putamen, part of the anterior limb of the internal capsule, the lentiform nucleus, and the external capsule. Main cortical branches of the middle cerebral artery supply the lateral surfaces of the cerebral cortex from the anterior portion of the frontal lobe to the posterolateral occipital lobe.

Although the posterior circulation is smaller and usually supplies only 20% of the brain, it supplies the brainstem (which is critical for normal consciousness, movement, and sensation), cerebellum, thalamus, auditory and vestibular centers of the ear, medial temporal lobe, and visual occipital cortex. The posterior circulation is derived from the two vertebral arteries that ascend through the transverse processes of the cervical vertebrae. The vertebral arteries enter the cranium through the foramen magnum and supply the cerebellum by the posterior inferior cerebellar arteries. They join to form the basilar artery, which branches to form the posterior cerebral arteries. Some variants exist, importantly, the fetal origin posterior cerebral artery, which is where the posterior cerebral artery is actually fed by the anterior circulation.

The extent of injury in either an anterior or a posterior stroke depends on both the vessel involved and the presence of collateral blood flow distal to the vessel occlusion. A patient with excellent collateral blood flow from the contralateral hemisphere may have minimal clinical deficits despite a complete carotid occlusion. By contrast, a patient with poor collateral flow may have hemiplegia with the same lesion.

**CLINICAL FEATURES**

**Ischemic Stroke**

The signs and symptoms of an ischemic stroke may appear suddenly and without warning or may have a stuttering, insidious onset. Disruption of the flow to one of the major vascular limbs of the cerebral circulation will result in physiologic disruption to the anatomic area of the brain supplied by that blood vessel. Ischemic strokes can be classified as anterior or posterior circulation strokes, depending on the vasculature involved. The presence of neurologic deficits is highly dependent on collateral flow. In addition to the vascular supply involved, ischemic strokes can be further described by the temporal presentation of their neurologic deficits.

A "stroke in evolution" is one in which focal neurologic deficits worsen over the course of minutes or hours. Approximately 20% of anterior circulation strokes and 40% of posterior circulation strokes will show evidence of progression. Anterior circulation strokes may progress within the first 24 hours, whereas posterior strokes may progress for up to 3 days. Propagation of thrombus is postulated as a likely mechanism for progression. With anterior circulation strokes (involving variously and primarily the carotid, anterior, and middle cerebral arteries), the clinical presentation rarely includes complete loss of consciousness unless the lesion occurs in the previously unaffected hemisphere of a patient who has experienced a previous contralateral stroke.

Occlusions in the anterior cerebral artery mainly affect frontal lobe function. The patient has altered mentation coupled with impaired judgment and insight, as well as the presence of primitive grasp and suck reflexes on physical examination. Bowel and bladder incontinence may be features of anterior cerebral artery stroke. Paralysis and hyposthesia of the lower limb opposite the site of the lesion are characteristic. Leg weakness is more pronounced than arm weakness in anterior cerebral distribution stroke. Apraxia or clumsiness in the patient’s gait also may be noted.

Marked motor and sensory disturbances are the hallmarks of occlusion of the middle cerebral artery. They occur on the side of the body contralateral to the side of the lesion and usually are worse in the arm and face than the leg. Such disturbances may involve only part of an extremity or the face but almost always are accompanied by numbness in the same region as that of the motor loss. Hemianopsia, or blindness in one-half of the visual field, occurs ipsilateral to the lesion. Agnosia, or the inability to recognize previously known subjects, is common, and aphasia may be present if the lesion occurs in the dominant hemisphere. Patients often have a gaze preference toward the affected hemisphere because of disruption of the cortical lateral gaze centers.

Aphasia, a disorder of language in which the patient articulates clearly but uses language inappropriately or understands it poorly, also is common in dominant-hemisphere stroke. Aphasia may be expressive, receptive, or a combination of both. Wernicke’s aphasia occurs when the patient is unable to process sensory input, such as speech, and thus fails to understand verbal communication (receptive aphasia). Broca’s aphasia refers to the inability to communicate verbally in an effective way, even though understanding may be intact (expressive aphasia). Aphasia should be distinguished from dysarthria, which is a motor deficit of the mouth and speech muscles; the dysarthric patient articulates poorly but understands words and word choices. Aphasia is important to recognize because it usually localizes a lesion to the dominant (usually left) cerebral cortex in the middle cerebral artery distribution. Aphasia and dysphasia are terms that are used interchangeably but must be distinguished from dysphagia, which is difficulty in swallowing.

Pathology in the vertebrobasilar system (ie, posterior circulation strokes) can cause the widest variety of symptoms and as a result may be the most difficult to diagnose. The symptoms reflect CN deficits, cerebellar involvement, and involvement of neurosensory tracts. The brainstem also contains the reticular activating system, which is responsible for mediating consciousness, and the mesial centers. Unlike those with anterior circulation strokes, patients with posterior circulation stroke can have loss of consciousness and frequently have nausea and vomiting. The posterior cerebral artery supplies portions of the parietal and occipital lobes, so vision and thought processing are impaired. Visual agnosia, the inability to recognize seen objects, may be a feature, as may alexia, the inability to understand the written word. A third nerve palsy may occur, and the patient may experience homonymous hemianopsia. One of the more curious facets of this syndrome is that the patient may be unaware of any visual problem (visual neglect). Vertigo, syncope, diplopia, visual field defects, weakness, paralysia, dysarthria, dysphagia, spasticity, ataxia, or nystagmus may be associated with vertebrobasilar artery insufficiency. Posterior circulation strokes also demonstrate crossed deficits, such as motor deficits on one side of the body and sensory loss on the other. In anterior circulation strokes, by contrast, abnormalities are always limited to one side of the body.

A focused neurologic examination should assess level of consciousness, speech, CN function, motor and sensory function, and cerebellar function. Level of consciousness and floruit of speech can be rapidly assessed in a dialogue with the patient to determine the presence of dysarthria or aphasia. The head should be evaluated for signs of trauma. Pupillary size and reactivity and extraocular movements provide important information about brainstem function, particularly CN III through CN V; an abnormal third nerve function may be the first sign of tentorial herniation. Gaze preference suggests brainstem or cortical involvement. Central facial nerve weakness from a stroke should be distinguished from the peripheral causes of CN VII weakness. With a peripheral lesion, the patient is unable to wrinkle the forehead. Assessment of facial sensation, eyebrow elevation and squinting, smiling symmetry, gross auditory acuity, gag reflex, shoulder elevation, sternocleidomastoid strength, and tongue protrusion complete the CN evaluation.
Motor and sensory testing is performed next. Muscle tone can be assessed by moving a relaxed limb. Proximal and distal muscle group strength is assessed against resistance. Pronator drift of the arm is a sensitive sign of motor weakness and can be tested simultaneously by having the patient sit with eyes closed and arms outstretched, with palms toward the ceiling, for 10 seconds. Asymmetrical sensation to pain and light touch may be subtle and difficult to detect. Double simultaneous extinction evaluation tests for sensory neglect and can be easily performed by simultaneously touching the right and left limbs. The patient may feel both the right and left sides being touched individually but may not discern touch on one side when both are touched simultaneously. Similarly, the ability to discern a number gently scratched on a forearm, graphesthesia, is another easily tested cortical parietal lobe function. These tests can help differentiate a pure motor deficit of a lacunar stroke from a sensorimotor middle cerebral artery deficit.

Cerebellar testing and the assessment of reflexes and gait complete the examination. Finger-to-nose and heel-to-shoe evaluations are important tests of cerebellar functions. Asymmetry of the deep tendon reflexes or unilateral Babinski’s sign may be an early finding of corticospinal tract dysfunction. Gait testing is commonly omitted yet is an informative part of the neurologic examination when it can be safely performed. Observing routine ambulation and heel-to-toe walking can assess for subtle ataxia, weakness, or focal cerebellar lesions.

Several prehospital stroke scales have been created to assist emergency medical service (EMS) personnel with the rapid assessment of potential stroke patients. Many of these prehospital stroke scales have been prospectively validated for their accuracy in stroke detection. Two of the more commonly used scales include the Cincinnati Prehospital Stroke Scale (Fig. 91.1) and Los Angeles Prehospital Stroke Screen (Fig. 91.2).

The National Institutes of Health Stroke Scale (NIHSS) is a useful and rapid tool for quantifying neurologic deficit in patients with stroke and can be used in determining treatment options (Table 91.1). NIHSS scores have been shown to be reproducible and valid and to correlate well with the amount of infarcted tissue on computed tomography (CT) scan. The baseline NIHSS score can identify patients who are appropriate candidates for fibrinolytic therapy, as well as those at increased risk for hemorrhage, although it is possible for patients to have disabling strokes with an NIHSS of zero (severe truncal ataxia). In addition, it has been used as a prognostic tool to predict outcome and is currently being used by some stroke centers to stratify patients for entry into treatment trials.

**Hemorrhagic Stroke**

The classic presentation of ICH is the sudden onset of headache, vomiting, severely elevated BP, and focal neurologic deficits that progress over minutes. Similar to ischemic stroke, ICH is often associated with a motor and sensory deficit contralateral to the brain lesion. Almost 40% of patients will demonstrate significant growth in hemorrhage volume within the first few hours.

Although headache, vomiting, and coma are common, many patients do not have these findings, and the clinical presentation can be identical to that of patients with ischemic stroke; the two cannot be reliably differentiated in the absence of neuroimaging.

Ongoing assessment of airway and mental status is of paramount importance in patients with ICH because precipitous deterioration is always a possibility. Emergency airway management requires careful judgment: On the one hand, airway control can prevent aspiration, hypoxia, and hypercarbia; on the other, sedation and paralysis can make it difficult to follow the neurologic examination, which can help monitor for hemorrhage expansion, elevated intracranial pressure (ICP), seizure activity, and brainstem herniation.

As with ischemic stroke, a careful neurologic examination is important in localizing the region and extent of injury. Baseline NIHSS and Glasgow Coma Scale scores can be used to assess stroke severity, although the Glasgow Coma Score (GCS) may be more practical to follow for neurologic deterioration (Table 91.2). In addition, serial examinations can detect early changes that may suggest ongoing bleeding during the acute phase. The ICH score can predict mortality (Table 91.3).

Poor prognostic indicators for patients with ICH include a decreased level of consciousness on arrival, intraventricular hemorrhage, and large ICH volume, all of which can be assessed in the emergency department (ED) (Fig. 91.3).

**DIFFERENTIAL DIAGNOSIS**

**Ischemic Stroke**

Extra-axial collections of blood secondary to trauma can mimic stroke. An epidural or subdural hematoma can cause an altered mental status, focal neurologic signs, and rapid progression to coma. Elders, who represent the age group at highest risk for stroke, can be victims of recurrent falls that lead to chronic subdural hematomas. Carotid dissection may occur after neck trauma or sudden hyperextension and may be associated with focal neurologic signs and symptoms, as with an aortic dissection that extends into the carotid arteries.

Other structural lesions that may cause focal neurologic signs include brain tumors and abscesses. Air embolism should be suspected in the setting of marked atmospheric pressure changes, such as in scuba diving or during medical procedures or injuries that may allow air into the vascular system. Seizures, altered mental status, and focal neurologic findings also may be manifestations of air embolism.

Metabolic abnormalities also can mimic stroke syndromes. Hypoglycemia often is responsible for an altered mental status and is a well-known cause of sustained focal neurologic symptoms that can persist for several days. Wernicke’s encephalopathy causes ophthalmoplegia, ataxia, and confusion that can be mistaken for signs of cerebellar infarction.

Migraine may present with focal neurologic findings, with or without headache. A seizure followed by Todd’s postictal paralysis may mimic stroke. Bell’s palsy, labyrinthitis, vestibular neuronitis, peripheral nerve palsy, and demyelinating diseases may all mimic stroke. Ménière’s disease may be difficult to distinguish from a posterior circulation stroke or TIA. Dizziness, vertigo, hearing loss, and tinnitus in Ménière’s disease are common, whereas...
nodosa, lupus, and other types of vasculitis may cause stroke syndromes.

Cerebral venous sinus thrombosis (CVST) is another cause of focal neurologic symptoms that most commonly affects the superior sagittal sinus and lateral sinuses (see Chapter 93). The diagnosis of CVST can be difficult because of the nonspecific nature of symptoms, as well as the variable time frame of symptom onset (from hours to a few weeks). Patients may have generalized headaches, nausea, vomiting, paresis, visual disturbances, depressed

Difficulties with vision or speech or other focal symptoms are uncommon.

Like stroke, giant cell arteritis is a disease of older adults. It may cause severe headache, visual disturbances, and, rarely, aphasia and hemiparesis. Other symptoms include intermittent fever, malaise, jaw claudication, morning stiffness, and myalgias. The diagnosis should be suspected in patients with a very high erythrocyte sedimentation rate (ESR) and is confirmed by temporal artery biopsy. Collagen vascular diseases such as polyarteritis

<table>
<thead>
<tr>
<th>ITEM</th>
<th>SCORING DEFINITIONS</th>
<th>SCORE</th>
</tr>
</thead>
</table>
| 1a. Level of consciousness (LOC) | 0 = Alert and responsive  
1 = Arousable to minor stimulation  
2 = Arousable only to painful stimulation  
3 = Reflex responses or unarousable | | |
| 1b. LOC-related questions: Ask patient’s age and month. Must be exact. | 0 = Both correct  
1 = One correct (or dysarthria, intubated, foreign language)  
2 = Neither correct | | |
| 1c. Commands: Open and close eyes, grip and release nonparetic hand. (Other one-step commands or mimic also acceptable.) | 0 = Both correct (acceptable if impaired by weakness)  
1 = One correct  
2 = Neither correct | | |
| 2. Best gaze: Horizontal EOM by voluntary or doll’s eye maneuver. | 0 = Normal  
1 = Partial gaze palsy; abnormal gaze in one or both eyes  
2 = Forced eye deviation or total paresis that cannot be overcome by doll’s eye maneuver | | |
| 3. Visual field: Use visual threat if necessary. If monocular, score field of good eye. | 0 = No visual loss  
1 = Partial hemianopsia, quadrantanopia, extinction  
2 = Complete hemianopsia  
3 = Bilateral hemianopsia or blindness | | |
| 4. Facial palsy: If patient is stuporous, check symmetry of grimace to pain. | 0 = Normal  
1 = Minor paralysis, flat NLF, asymmetrical smile  
2 = Partial paralysis (lower face = UMN lesion)  
3 = Complete paralysis (upper and lower face) | | |
| 5. Motor arm: Arms outstretched 90 degrees (sitting) or 45 degrees (supine) for 10 seconds. Encourage best effort. Indicate paretic limb in score box. | 0 = No drift for 10 seconds  
1 = Drift but does not hit bed  
2 = Some antigravity effort, but cannot sustain  
3 = No antigravity effort, but even minimal movement counts  
4 = No movement at all  
X = Unable to assess owing to amputation, fusion, fracture, and so on | L or R |
| 6. Motor leg: Raise leg to 30 degrees (from supine) for 5 seconds. Indicate paretic limb in score box. | 0 = No drift for 5 seconds  
1 = Drift but does not hit bed  
2 = Some antigravity effort, but cannot sustain  
3 = No antigravity effort, but even minimal movement counts  
4 = No movement at all  
X = Unable to assess owing to amputation, fusion, fracture, and so on | L or R |
| 7. Limb ataxia: Check finger-nose-finger, heel-shin position sense; and score only if out of proportion to paralysis. | 0 = No ataxia (or aphasic, hemiplegic)  
1 = Ataxia in upper or lower extremity  
2 = Ataxia in upper and lower extremity  
X = Unable to assess owing to amputation, fusion, fracture, and so on | L or R |
| 8. Sensory: Use safety pin. Check grimace or withdrawal if patient is stuporous. Score only stroke-related losses. | 0 = Normal  
1 = Mild-moderate unilateral loss but patient aware of touch (or aphasic, confused)  
2 = Total loss, patient unaware of touch; coma, bilateral loss | | |
| 9. Best language: Describe cookie jar picture, name objects, read sentences. May use repeating, writing, stereognosis. | 0 = Normal  
1 = Mild-moderate aphasia (speech difficult to understand but partly comprehensible)  
2 = Severe aphasia (almost no information exchanged)  
3 = Mute, global aphasia, coma; no one-step commands | | |
| 10. Dysarthria: Read list of words. | 0 = Normal  
1 = Mild-moderate; slurred but intelligible  
2 = Severe; unintelligible or mute  
X = Intubation or mechanical barrier | | |
| 11. Extinction or neglect: Simultaneously touch patient on both hands, show fingers in both visual fields, ask about deficit, left hand. | 0 = Normal, none detected (visual loss alone)  
1 = Neglects or extinguishes to double simultaneous stimulation in any modality (visual, auditory, sensation, spatial, body parts)  
2 = Profound neglect in more than one modality | | |

level of consciousness, seizures, or even symptoms generally ascribed to psychiatric disorders (such as, depression). Depending on the location of the thrombus, physical examination of the patient may reveal papilledema, proptosis, or palsy of CNs III, IV, and VI, as well as other focal neurologic signs and symptoms. Risk factors for CVST include trauma, infectious processes, hypercoagulable states, low-flow states, compression of the venous sinus, dehydration, various drugs (such as, androgens, “ecstasy,” and oral contraceptives), and pregnancy or the postpartum state.

**Hemorrhagic Stroke**

The differential diagnosis for ICH is similar to that for ischemic stroke; considerations include migraine, seizure, tumor, abscess, hypertensive encephalopathy, and trauma. Hypertensive encephalopathy and migraine also can manifest with headache, nausea, and vomiting, although focal neurologic signs are less common in these entities. With hypertensive encephalopathy, patients usually exhibit marked elevation in BP and other evidence of end-organ injury, such as proteinuria, cardiomegaly, papilledema, and malignant hypertensive retinopathy. These patients usually improve significantly with treatment of their hypertension. The posterior reversible encephalopathy syndrome is an important subset of hypertensive encephalopathy presentations and has characteristic CT or magnetic resonance imaging (MRI) changes.

Once ICH is appreciated on neuroimaging, it can be difficult to determine the underlying cause. Primary ICH typically manifests as a parenchymal hematoma with new onset neurologic symptoms. Patients with hemorrhagic transformation of an ischemic stroke may have recurrence or worsening of previously established deficits. Patients with known underlying cancer, or perihematoma edema out of proportion to the hemorrhage, should be considered for hemorrhage into a metastasis or primary tumor. Finally, patients with known underlying venous thromboembolic risk factors may have underlying CVST.

DIAGNOSTIC TESTING

Ischemic Stroke

Although clinical data can help establish the diagnosis, cause, and location of the stroke, confirmatory diagnostic tests are often required to establish the final cause or to eliminate other causes for the deficits. The immediate evaluation includes cranial imaging, an electrocardiogram (ECG) and hematologic testing, particularly blood glucose determination.

An emergent noncontrast cranial CT is the standard initial imaging technique for evaluating a patient with a potential stroke. It can quickly differentiate an ischemic stroke from ICH and other mass lesions. This information is crucial to the subsequent therapeutic decisions that will be rapidly made. A CT scan can identify almost all parenchymal hemorrhages larger than 1 cm in diameter and it has a high sensitivity for the detection of SAH. In a majority of ischemic strokes, gross signs of infarction will not appear on routine CT scans for at least 6 to 12 hours, depending on the size of the infarct. However, subtle, early ischemic changes have been noted in up to 67% of noncontrast CT scans within the first 3 hours. These early ischemic changes include the hyperdense artery sign (acute thrombus in a vessel), sulcal effacement, loss of the insular ribbon, loss of gray-white interface, mass effect, and acute hypodensity (Fig. 91.4). In addition, CTA can be used to identify the presence of intravascular thrombosis, vasculature dissection, or stenosis. In cases in which arterial dissection is suspected, imaging with MRA or CTA is indicated.

The clinical importance of early ischemic CT findings with regard to fibrinolytic therapy within 3 hours of symptom onset is questionable, because the ability of treating physicians to reproducibly identify these findings is poor and their clinical significance is questionable. Only acute hypodensity and mass effect have been shown to be associated with an increased risk of ICH after fibrinolysis (over that in treated patients without these findings). However, these findings do not exclude patients from fibrinolytic therapy, which is associated with an improved neurologic outcome. Patients with a hyperdense artery sign and acute hypodensity of one-third of the middle cerebral artery distribution tend to have a poorer prognosis; however, their outcomes are still better with tPA treatment than without such treatment.

MRI can visualize ischemic infarcts earlier and identify acute posterior circulation strokes more accurately than CT, and it may be as effective as CT in identifying ICH. However, availability, difficulty in accessing critically ill patients, and scan time limit the use of MRI in acute stroke. Advances in MRA technology have allowed a noninvasive method of demonstrating large-vessel occlusions of the anterior and posterior circulation, although small intracranial vascular occlusions may not be readily apparent. With the improvements in MRI and MRA speed and resolution, some stroke centers are replacing CT protocols with limited “stroke protocol” MRI or MRA as the initial imaging modality of choice. The choice of initial cranial imaging modality is highly dependent on the speed with which these scans can be performed and interpreted at each individual center.

Diffusion-weighted imaging (DWI) and perfusion-weighted imaging (PWI) are MRI techniques that take minutes to perform and may allow differentiation between reversible and irreversible neuronal injury. Other potential imaging modalities include CTA and perfusion scans. In CTA, a CT scan is enhanced by an intravenous (IV) contrast agent to better define the vasculature of the brain. Areas of vascular stenosis and occlusion can be visualized with this technique. This information can then be used by interventionalists to determine whether a lesion is amenable to endovascular thrombectomy. Also requiring IV contrast, perfusion CT scans can reveal perfusion deficits within different regions of the brain. In addition, CTA and perfusion CT can differentiate reversible from irreversible ischemic insults.

An ECG is indicated in all patients with acute ischemic stroke, because atrial fibrillation and acute myocardial infarction are associated with up to 60% of all cardioembolic strokes. The hematologic evaluation includes a complete blood count with platelet count, prothrombin time (including international normalized ratio [INR]), partial thromboplastin time, cardiac enzymes, and serum glucose measurement. Elevated blood viscosity, even when hematocrit levels are not frankly polycythemic, can affect blood flow and prognosis. A platelet count can identify thrombocytopenia or thrombocytopenia, which may precipitate a thrombosis or hemorrhage. Coagulation studies are especially helpful to guide management for patients in whom anticoagulation is being considered or for patients with a hemorrhagic stroke.
Other ancillary diagnostic tests to consider include an echocardiogram, carotid duplex scan, and angiogram. Some centers are performing these studies as part of a TIA observation unit protocol to exclude a patent foramen ovale or valvular vegetation in those patients in whom a cardioembolic stroke is suspected. An echocardiogram should also be performed in patients with no obvious cause for their stroke. Finally, conventional angiography can demonstrate stenosis or occlusion of both large and small blood vessels of the head and neck. It can detect subtle abnormalities, such as with dissection, that may not be demonstrated with noninvasive imaging techniques.

**Transient Ischemic Attack**

Patients with new-onset TIAs should receive an expedited evaluation and treatment owing to the substantial short-term risk of stroke and other adverse events. Emergency neuroimaging, vascular imaging (such as, with a carotid Doppler study, MRA, or CTA), electrocardiography, and basic blood tests should be performed. A medically or surgically treatable cause for TIAs (eg, high-grade carotid stenosis, mural thrombus) should be sought, which would require in-hospital treatment such as anticoagulation, stenting, or carotid endarterectomy.

**Hemorrhagic Stroke**

The hematologic evaluation for the patient with hemorrhagic stroke should be performed in the same manner as for the patient with ischemic stroke. Particular attention should be directed to uncovering the presence of a coagulopathy. A drug screen should be obtained to evaluate for use of sympathomimetics if substance abuse is suspected. Increased sympathetic outflow secondary to the hemorrhage may lead to an increase in dysrhythmias. Dysrhythmias also may signal impending brainstem compression from an expanding hemorrhage.

As in ischemic stroke, the cranial CT scan is the diagnostic test of choice to evaluate for an ICH. The noncontrast CT scan will reliably diagnose patients with clinically relevant acute ICH. Hemorrhages that are several days old may not be as apparent as acute hematomas and appear as isodense regions.

Also, as with ischemic stroke, advanced neuroimaging modalities are gaining favor in ICH. CTA produces high-quality images of the larger arterial vessels and can help exclude secondary causes, such as aneurysm, AVM, or fistula. Some patients with primary ICH show contrast extravasation on CTA, and such patients are at particularly high risk of ongoing bleeding and hematoma expansion. A venous phase can be added to this study (computed tomography venography [CTV]) to evaluate for CVST. A MRI can help detect underlying lesions (such as, tumor) and may offer better resolution for evaluating perihematomal edema. When available, MRA and magnetic resonance venography (MRV) can be used in place of CTA and CTV.

** MANAGEMENT **

**Ischemic Stroke**

With a focus on rapid recognition, evaluation, and treatment of stroke, many hospitals have streamlined care to meet recommended time goals (Table 91.4). This has led to the development of stroke protocols, critical pathways, and acute interventional stroke teams that may even be deployed in the field before the patient arrives at the ED.

In the prehospital setting, the focus should be on ensuring central nervous system (CNS) oxygenation and perfusion, rapid identification, early hospital notification, and rapid transport. Although it is unusual for patients with ischemic stroke to be unresponsive on presentation, their ability to communicate may be altered by dysphasia. After an ischemic stroke, patients usually can maintain their airway unless the brainstem is affected or significant cerebral edema is compressing the opposite hemisphere. Patients with intact protective airway reflexes should receive oxygen if they are hypoxic (oxygen saturation less than 95%), and a monitor and IV line should be established. Routine oxygen supplementation of normoxic stroke patients should be avoided.

Overhydration should be avoided to prevent cerebral edema. By contrast, dehydration may lead to decreased cerebral perfusion, and saline infusion should be given if dehydration is suspected. Dextrose-containing solutions should be avoided in normoglycemic patients suspected of having had a stroke because elevated blood glucose levels may worsen an ischemic deficit. Out-of-hospital personnel should attempt to rapidly ascertain the patient’s blood sugar; if this is not possible, glucose should be given when hypoglycemia is strongly suspected with an understanding that hyperglycemia may be neurotoxic. Electrocardiographic monitoring is recommended to identify life-threatening arrhythmias and atrial fibrillation.

The circumstances surrounding the stroke as well as concomitant medical conditions should be ascertained. A key part of the initial information on stroke patients is the prehospital providers’ documentation of the exact time the patient was last seen to be neurologically normal and the level of neurologic functioning. This is especially important because reversible defects may completely resolve by the time the patient has arrived at the hospital.

The level of consciousness, gross focal motor deficits, difficulty with speech, clumsiness, facial asymmetry, and any other focal deficits should be noted. Prehospital stroke scales assist in identifying patients who have had a stroke and who are potential candidates for fibrinolytic therapy. Early recognition, notification, and transport by EMS are associated with delivery of fibrinolytic treatment and improved patient outcomes.

In the ED setting, the vital signs should be reassessed on an ongoing basis because patients may rapidly deteriorate even with subacute stroke. Some stroke patients are found at home 1 or 2 days after the event has occurred and may have concomitant illnesses, such as aspiration pneumonia, dehydration, hypothermia, rhabdomyolysis, or myocardial ischemia. Fever necessitates an evaluation to identify sources of infection, followed by prompt institution of treatment. Even minor degrees of hyperthermia have been associated with increased neurologic injury. Oral medications (and food) should be withheld until some form of swallowing assessment has been performed, given the risk of aspiration in patients with an acute stroke.

Blood Pressure Management

The management of BP in patients with acute ischemic stroke and TIA is controversial because of limited data. Current guidelines for the management of hypertension in patients with acute ischemic stroke recommend that antihypertensive treatment be reserved for those with markedly elevated BPs, unless fibrinolytic therapy is planned or specific medical indications are present. These medical indications include acute myocardial infarction, aortic dissection, hypertensive encephalopathy, and severe left ventricular heart failure.

Oral or parenteral agents are withheld unless the patient’s systolic pressure is greater than 220 mm Hg, diastolic pressure is greater than 120 mm Hg, or mean arterial pressure (MAP) is greater than 130 mm Hg (Box 91.2). If parenteral agents are used, labelatal 10 to 20 mg IV push, or a calcium channel blocker (eg, nicardipine starting at 5 mg/hour IV), is favored because of ease of titration and limited effect on cerebral blood vessels. Sublingual nifedipine or sublingual nitroglycerin are not recommended, because either agent can produce a precipitous drop in BP.

If fibrinolytic therapy is planned, stringent control of BP is indicated to reduce the potential for intracranial hemorrhage after the thrombolytic is administered (see Box 91.2).

Thrombolytic therapy is not recommended for patients whose systolic pressure is consistently higher than 185 mm Hg or whose diastolic pressure is 110 mm Hg at the time of treatment. Simple measures can be used to try lowering BP below this level. Recommended approaches include the use of IV labelatal 10 to 20 mg or continuous nicardipine. Once thrombolytic therapy has been initiated, BP must be monitored closely and hypertension treated aggressively.

Just as problematic as high BP can be, low BP can be quite detrimental to patients with ischemic stroke. Normally normotensive stroke patients with low BP or normally hypertensive stroke patients with low or even low-normal BP are given a fluid bolus to try to increase cerebral perfusion. This is especially important in patients in a dehydrated state. If initial fluid challenge is ineffective, the patient may require vasopressor therapy (eg, with dopamine) to gradually increase MAP and improve cerebral perfusion.

Thrombolytic Therapy

To date, the only IV thrombolytic agent approved by the U.S. Food and Drug Administration (FDA) for treatment of patients with acute ischemic stroke is the recombinant tissue plasminogen activator (rtPA), alteplase (Activase). Approval was initially based on the results of the National Institute of Neurological Disorders and Stroke (NINDS) trial, although subsequent analysis of other studies has supported its use.15,16 There was initial concern regarding the safety of alteplase when used in community practice; however, a meta-analysis of non–trial-related use in community practice has demonstrated efficacy and safety similar to that reported in the NINDS trial; this was also replicated within a cluster randomized controlled trial performed in Michigan.17 The recommended dose for rtPA is 0.9 mg/kg IV to a maximum of 90 mg (10% of the dose given as a bolus followed by an infusion lasting 60 minutes). Although the initial recommended time window for IV rtPA administration was 3 hours because the patient was last known to be at their neurologic baseline, a subsequent study has demonstrated the usefulness of IV rtPA at 3 to 4.5 hours in a carefully selected subgroup of acute ischemic stroke patients (Table 91.5 and Box 91.3). A larger open-label randomized trial focusing on patients presenting with “reasonable uncertainty” regarding the expected benefit of rtPA found reduced death and dependency at 6 months; a large proportion of patients in this study were quite old, or had old stroke (>4.5 hours), or both.18 These results should not influence clinical practice, because the bulk of the population included in this large trial was markedly different from the population of stroke patients who receive thrombolyis within the context of current guidelines.

The American Stroke Association recommends that rtPA be given within 60 minutes of arrival to appropriately selected ischemic stroke patients. Recent guidelines from the American College of Emergency Physicians concur but also emphasize that proper systems of care must also be in place to ensure safety and to maximize good outcomes.19

Studies suggest that patients with mild or rapidly resolving symptoms may still benefit from the use of IV rtPA, and a clinical trial is ongoing in this area. A promising early phase trial of tenecteplase was recently completed for patients with mild stroke and high-grade large-vessel stenosis. However, this strategy cannot be recommended yet if feasible clinicians should consider urgent transfer of patients with mild symptoms and high grade stenosis for potential reperfusion strategies, including mechanical

**Box 91.2**

**Emergency Antihypertensive Therapy for Acute Ischemic Stroke**

**INDICATION THAT PATIENT IS ELIGIBLE FOR TREATMENT WITH INTRAVENOUS RECOMBINANT TISSUE PLASMINOGEN ACTIVATOR OR OTHER ACUTE REPERFUSION INTERVENTION**

**Blood Pressure Level**

Systolic >185 mm Hg or diastolic >110 mm Hg
- Labetalol 10 to 20 mg IV over 1 to 2 minutes; may repeat 1 time
- Nicardipine infusion, 5 mg/hr; titrate up by 2.5 mg/hr at 5- to 15-minute intervals, maximum dose 15 mg/hr; when desired BP attained, reduce to 3 mg/hr
- Other agents (hydralazine, enalaprilat, and so on) may be considered when appropriate.

If BP does not decline and remains >185/110 mm Hg, do not administer rtPA.

**MANAGEMENT OF BLOOD PRESSURE DURING AND AFTER TREATMENT WITH RECOMBINANT TISSUE PLASMINOGEN ACTIVATOR OR OTHER ACUTE REPERFUSION INTERVENTION**

Monitor BP every 15 minutes during treatment and then for another 2 hours, then every 30 minutes for 6 hours, and then every hour for 16 hours.

**Blood Pressure Level**

Systolic 180 to 230 mm Hg or diastolic 105 to 120 mm Hg
- Labetalol 10 mg IV over 1 to 2 minutes; may repeat every 10 to 20 minutes; maximum dose of 300 mg
- Labetalol 10 mg IV followed by an infusion at 2 to 8 mg/min
- Systolic >230 mm Hg or diastolic 121 to 140 mm Hg
- Labetalol 10 mg IV over 1 to 2 minutes; may repeat every 10 to 20 minutes; maximum dose of 300 mg
- Nicardipine infusion, 5 mg/hr; titrate up to desired effect by increasing 2.5 mg/hr every 5 minutes to maximum of 15 mg/hr

If BP not controlled, consider sodium nitroprusside.

**BP:** Blood pressure; **IV:** intravenous; **rtPA:** recombinant tissue plasminogen activator.

BOX 91.3
Fibrinolytic Therapy for Acute Ischemic Stroke in the 3- to 4.5-Hour Time Window Inclusion and Exclusion Criteria

INCLUSION CRITERIA
Diagnosis of ischemic stroke causing measurable neurological deficit
Onset of symptoms within 3 to 4.5 hours before beginning treatment

RELATIVE EXCLUSION CRITERIA
Older than 80 years old
Severe stroke (NIHSS > 25)
Taking an oral anticoagulant regardless of INR
History of both diabetes and prior ischemic stroke

Intravenous (IV) tPA is not recommended when the time of stroke onset cannot be ascertained reliably, including strokes recognized on awakening. Although the aggregate risk of symptomatic ICH is about 6% in trials and observational studies, each individual patient will have differing probabilities of benefits and risks. Optimal methods of communicating benefits and risks promptly have not been developed or widely disseminated, because all reviewed decision aids have methodological deficiencies. However, younger patients and milder strokes (NIHSS < 10) clearly have a lower risk of SICH. It is reasonable to adjust outcome expectations when discussing benefits and risks with older patients with more severe strokes (including significant early CT changes). The risk of severe disability and death is quite high in this population with or without fibrinolysis. Prompt fibrinolysis of severe strokes will shift the outcomes of a population of treated patients toward less disability. Several recent trials suggest these outcomes can be further improved with careful selection of patients for endovascular rescue therapy.

Endovascular Rescue Therapy
The results of several concurrent trials investigating prompt endovascular rescue therapy (usually following IV thrombolysis) versus medical management were published in late 2014 and early 2015. These studies have conclusively demonstrated that patients with severe strokes and evidence of proximal large vessel occlusions have significantly better functional outcomes when treated with the new generation devices. Each of these trials used different imaging and clinical selection criteria, although the presence of a proximal occlusion and prompt treatment, preferably within 3 hours, were common to all of the protocols. These trials emphasize the need for better regionalization of stroke care to reduce the time to definitive reperfusion. Unlike acute ischemic stroke, non-acute cases of intracranial occlusions are best treated with medical therapy and not permanent intracranial stents.

Intra-arterial thrombolysis currently does not have a defined role in the treatment of acute ischemic stroke.
provide benefit. Multidisciplinary care by specially trained care teams appears to be similar to that for ischemic stroke, including determination of care management facilities. Out-of-hospital management is transport to a care center with rapid neuroimaging and intensive care management of patients with acute ischemic stroke, and current AHA quality measures and public reporting.33 It may be that any reduction in risk of subsequent ischemic stroke is balanced by an increased risk of hemorrhagic stroke. To date, no studies have definitively established the efficacy of anticoagulants in the management of patients with acute ischemic stroke, and current AHA guidelines recommend against the routine use of heparinoids in this population.4 However, heparin is sometimes considered by vascular neurologists in select patients at high risk for stroke progression, including patients with crescendo TIA or TIA from a cardioembolic source (eg, atrial fibrillation, patients with a high-grade carotid artery stenosis, patients with posterior circulation TIA, and patients with evolving strokes). Heparin or LMWH is often instituted to treat carotid and vertebral artery dissection, unless a contraindication such as intracranial extension is present. If a dissection is diagnosed and the patient has no symptoms of ischemia, treatment with antiplatelet therapy alone may be an option. Heparin therapy should not be initiated in patients with suspected endocarditis or in any patient until a CT scan has ruled out intracranial bleeding.

Anticoagulation

The use of therapeutic dosing of low–molecular-weight heparin (LMWH) or unfractionated heparin is now generally abandoned in the routine care of stroke patients; prophylactic dosing to prevent venous thromboembolism is a hospital level quality measure and publically reported.5 It may be that any reduction in risk of hemorrhagic stroke is balanced by an increased risk of hemorrhagic stroke. To date, no studies have definitively established the efficacy of anticoagulants in the management of patients with acute ischemic stroke, and current AHA guidelines recommend against the routine use of heparinoids in this population.4 However, heparin is sometimes considered by vascular neurologists in select patients at high risk for stroke progression, including patients with crescendo TIA or TIA from a cardioembolic source (eg, atrial fibrillation, patients with a high-grade carotid artery stenosis, patients with posterior circulation TIA, and patients with evolving strokes). Heparin or LMWH is often instituted to treat carotid and vertebral artery dissection, unless a contraindication such as intracranial extension is present. If a dissection is diagnosed and the patient has no symptoms of ischemia, treatment with antiplatelet therapy alone may be an option. Heparin therapy should not be initiated in patients with suspected endocarditis or in any patient until a CT scan has ruled out intracranial bleeding.

Intracerebral Hemorrhage

No specific therapy has been demonstrated to substantially improve the outcome of patients with ICH. One of the strongest predictors of mortality when considering ICH patients with comparable severity is the implementation of early care limitations. When health care providers initiate early do not resuscitate (DNR) orders, patients with otherwise equivalent prognoses are more likely to die. As a result, we believe that early prognostication in the ED should be avoided. Current evidence supports the benefit of aggressive medical care. Patients admitted to a specialized unit, patients who are expedited to the intensive care unit (ICU), those admitted on a weekday, and those treated more aggressively appear to have better neurologic outcomes.61-63 Therefore, even in the absence of therapies specifically proven in phase III trials, multidisciplinary care by specially trained care teams appears to provide benefit.

The patient with suspected ICH requires rapid assessment and transport to a care center with rapid neuroimaging and intensive care management facilities. Out-of-hospital management is similar to that for ischemic stroke, including determination of time of onset, concomitant medications, and application of a prehospital stroke scale.

Supportive care involving attention to airway management and perfusion is of the highest priority. Patients with hemorrhagic stroke are more likely to have an altered level of consciousness that may rapidly progress to unresponsiveness requiring emergent endotracheal intubation. After intubation, a short-acting medication for sedation should be considered so that a neurologic examination can be repeatedly performed and the findings evaluated. Standard care includes establishing IV access and cardiac monitoring. Evaluation of blood glucose and appropriate dextrose and naloxone administration are essential in any patient with altered mental status.

Patients seen early after symptom onset are at high risk of ongoing bleeding. Approximately 30% of such patients will have significant hematoma expansion on presentation, leading to neurologic deterioration and worse outcome. Major therapies aimed at reducing this risk include BP reduction, anticoagulation reversal, and hemostatic therapy.

BP control is commonly performed after ICH. This intervention is controversial, because hypertension may potentiate further bleeding, but lowering BP in a patient with chronic hypertension may decrease CBF, worsening brain injury. One randomized trial found that lowering systolic BP to below 140 reduced ongoing bleeding, but there was no change in neurologic outcome, suggesting that this therapy may not provide clinical benefit in unselected patients. A larger trial focused on functional outcomes demonstrated that prompt reduction to a systolic blood pressure (SBP) of 140 mm Hg may slightly reduce disability and was generally safe.36 The current consensus regarding management of ICH is to provide antihypertensive treatment with parental agents for systolic pressures higher than 160 to 180 mm Hg or MAP higher than 130 mm Hg. Recommended agents include labetalol, esmolol, nicardipine, clevidipine, and hydralazine.

Many patients are coagulopathic at the time of their ICH; and for patients on anticoagulants, emergency reversal will theoretically minimize the risk of further bleeding, although this is not backed up by clinical trial evidence. For patients on warfarin, reversal is achieved using IV vitamin K (10 mg IV or subcutaneously), supplemented with either fresh frozen plasma (FFP) (2 to 4 units) or prothrombin complex concentrate (PCC) (Kcentra 25 to 50 units/kg depending on INR—dosing varies for other PCCs by formulation).3 Of the new generation oral anticoagulants, at this time only dabigatran has a specific antidote (idarucizumab) proven to reverse coagulant effects in human clinical trials.43 Four-factor PCC is likely to be the most quickly available reversal agent for apixaban and rivaroxaban; hemodialysis will rapidly eliminate dabigatran from the circulation but is not generally practical for patients with serious bleeding.46 Hemostatic therapy (treatment with procoagulant agents; eg, recombinant activated factor VII in patients without baseline coagulopathy) was initially promising; however, a phase III trial showed no clinical benefit.

To consider other iatrogenic coagulopathies, post-thrombolytic symptomatic intracranial hemorrhage is a serious complication. Although various protocols have been employed for post-thrombolysis intracranial hemorrhage, a comparative observational study comparing reversal with FFP or cryoprecipitate versus conservative management (no reversal) demonstrated poor outcomes in both groups. Mortality was slightly higher in the reversal group, although this study only included 48 patients. Based on the limited evidence, at this point in time we would recommend administering cryoprecipitate (6 to 8 units) for thrombolytic associated ICH that occurs shortly (0 to 3 hours) after alteplase administration. Later ICH (3 hours to days) is unlikely to be associated with a persistent coagulopathy, because the fibrinogen depletion following alteplase administration is transient; therefore, reversal
agents appear to confer risk without a potential biological benefit in this time window.

Finally, the data on treatment of patients with spontaneous ICH who are on preexisting antiplatelet treatments, such as aspirin or clopidogrel, is conflicting. A small subgroup of an observational trial (27 patients) suggested patients receiving a platelet infusion within 12 hours of onset had an increased odds of a good functional outcome.\(^3\) At this time, the data do not support platelet transfusions in patients with spontaneous ICH being treated with antiplatelet agents, unless a new thrombocytopenia (platelet count <30,000) has also developed.

For patients with clinical or radiographic evidence of elevated ICP, therapies aimed at lowering ICP should be considered. First, neurosurgical consultation is obtained to evaluate the benefits of an external ventricular drain (EVD) placement or hematoma evacuation. Pending consultation, a number of medical therapies aimed at decreasing ICP are available; however, these interventions should not be used prophylactically.\(^1\) Hyperventilation can be a temporizing measure pending more definitive treatment. Mannitol moves fluid from the intracranial compartment, thereby reducing cerebral edema. Hypertonic saline (3% or 23.4%) can be used as an alternative to mannitol or in combination. Other experimental modalities include barbiturate coma and hypothermia.

Seizure activity can cause neuronal injury, elevations in ICP, and destabilization of an already critically ill patient. However, there is observational evidence that prophylactic administration of antiepileptic drugs (AEDs) may be harmful; therefore, AEDs should be reserved for patients with known or suspected seizure, including nonconvulsive seizures.\(^1\)

Surgical evacuation of the hematoma is not beneficial in most cases of non-cerebellar ICH. Selected patients with a sizable lobar hemorrhage that is proximal to the cortical surface and associated with progressive neurologic deterioration may benefit from surgical drainage. Recent studies have also suggested that minimally invasive surgery (eg, stereotactic insertion of a catheter) may provide some benefit to selected patients. For patients with cerebellar hemorrhage, surgery can be lifesaving, because the infratentorial space is much more limited and high ICP can disrupt vital brainstem functions. For this reason, many neurosurgeons will consider emergent surgery for patients with cerebellar hemorrhage within 48 hours of onset.

In cases of severe intraventricular hemorrhage or hemorrhages in the posterior fossae, the normal circulation of cerebrospinal fluid (CSF) can become interrupted, leading to the development of hydrocephalus. This condition is characterized by an abnormal rise in CSF volume. In such cases, neurosurgeons will often place a ventricular catheter. Some groups infuse thrombolytic agents through the catheter to help break up the clot and minimize the risk of hydrocephalus.

Finally, as with ischemic stroke, general supportive care should be provided to minimize neuronal injury. This includes treating hyperthermia (such as, with acetaminophen) and treating hyperglycemia with insulin.

**DISPOSITION**

**Ischemic Stroke and Transient Ischemic Attacks**

“Stroke center” definitions have been established, and there is a national certification process for primary stroke centers (PSCs) and comprehensive stroke centers (CSCs) in the United States. In broad terms, institutional certification as a PSC requires the establishment of a stroke infrastructure (ie, a stroke team, stroke unit, patient care protocols, and support services, including CT scanning and laboratory testing availability), as well as institutional administrative support and strong leadership.\(^4,9\) CSCs offer advanced imaging modalities, perform surgical and endovascular interventions, and maintain a core infrastructure, such as a stroke unit and stroke registry. The establishment of PSCs and CSCs is intended to improve outcomes for stroke patients by ensuring a high level of coordinated care.

The most recent level of stroke classification for hospitals is the acute stroke-ready hospital (ASRH). These hospitals are typically smaller facilities with lower stroke patient volumes. An ASRH is capable of establishing the initial stroke diagnosis, as well as providing acute stabilization and treatment. The use of teletechnologies between the ASRH and PSC/CSC will likely serve a pivotal role in support of clinical care. After initial stabilization and treatment, stroke patients will frequently be transferred to PSC or CSC institutions.\(^10\)

It is recommended that patients with symptoms consistent with an acute stroke be transported to emergency facilities capable of initiating fibrinolytic therapy within 1 hour of hospital arrival. At a minimum, this requires emergent CT capabilities, an institutional “acute stroke protocol,” and availability of a physician knowledgeable in the use of thrombolytic therapy. Intensive care monitoring and neurosurgery capabilities should be available within 2 hours of drug initiation, either at the treating hospital or by helicopter or ground transport to an appropriate health care facility.\(^11\)

In most cases, once the diagnosis of an acute stroke or stroke syndrome is established and the patient is stabilized, hospitalization will be necessary for further evaluation and treatment. Patients may deteriorate over the first 24 hours and require close in-hospital monitoring. Most patients can be managed on a general medical or telemetry unit, although there is evidence suggesting a benefit from admission to a stroke-specific unit. Patients with large acute hemispheric strokes (associated with increased risk of herniation) or with significant posterior circulation-related changes and those treated with a fibrinolytic agent should be monitored in a step-down or ICU for at least 24 hours.

In many centers, patients require admission to receive a prompt evaluation for TIA. However, some centers have developed ED observation unit protocols or rapid outpatient TIA clinics to ensure an expedited evaluation (see Chapter 66). One commonly used tool available to help select which TIA patients are at highest risk (and thus likely should be admitted) versus those at lowest

\(BP,\) Blood pressure.
Anterior circulation strokes result in contralateral hemiparesis of the face and body. Vertebrobasilar strokes result in ipsilateral CN deficits and contralateral hemiparesis. Posterior cerebral artery stroke causes ipsilateral CN III palsy and contralateral homonymous hemianopsia. Wallenberg's syndrome (lateral medullary syndrome) causes vertigo, Horner's syndrome, ipsilateral facial numbness, loss of corneal reflex, and contralateral loss of pain/temperature. Cervical artery dissection is a common cause of stroke in young patients; TIAs preceding stroke in these patients are often missed. The goal for eligible patients is to receive thrombolytics within 90 minutes of symptoms onset; the dose of alteplase is 0.9 mg per kg with 10% given as a bolus and the remaining 90% given over 1 hour. Acute ischemic stroke patients receiving alteplase are at risk of developing a spontaneous intracranial hemorrhage; the risk is lowest in patients with a low stroke score, no hypertension, no diabetes, and age younger than 70.

The majority of patients with an acute hemorrhagic stroke should be admitted to an ICU in which specialty consultation is available. If this is unavailable at the evaluating institution, the patient should be transported to an appropriate institution.

### KEY CONCEPTS

- Anterior circulation strokes result in contralateral hemiparesis of the face and body.
- Vertebrobasilar strokes result in ipsilateral CN deficits and contralateral hemiparesis.
- Posterior cerebral artery stroke causes ipsilateral CN III palsy and contralateral homonymous hemianopsia.
- Wallenberg's syndrome (lateral medullary syndrome) causes vertigo, Horner's syndrome, ipsilateral facial numbness, loss of corneal reflex, and contralateral loss of pain/temperature.
- Cervical artery dissection is a common cause of stroke in young patients; TIAs preceding stroke in these patients are often missed.
- The goal for eligible patients is to receive thrombolytics within 90 minutes of symptoms onset; the dose of alteplase is 0.9 mg per kg with 10% given as a bolus and the remaining 90% given over 1 hour.
- Acute ischemic stroke patients receiving alteplase are at risk of developing a spontaneous intracranial hemorrhage; the risk is lowest in patients with a low stroke score, no hypertension, no diabetes, and age younger than 70.
- In acute ischemic stroke, the patient and or their families should be informed of the risk and benefit of treatment with alteplase.
- Patients with a hemorrhagic stroke on coumadin should be promptly reversed using vitamin K and either FFP or PCC.
- Prognosis is worse in acute stroke in the setting of fever, hypotension, hypoxia, and hyperglycemia.
- Carotid Doppler, MRA, or CTA studies are recommended before discharge of a patient with TIA from the ED.
- Overly aggressive BP management should be avoided in patients with acute ischemic stroke.
- Accurate identification of the last time a patient was known to be at his or her neurologic baseline should be documented in all patients with stroke.
- IV alteplase followed by endovascular thrombectomy is recommended in patients with large anterior circulation artery occlusion.

REFERENCES

 consciousness with vomiting, visual changes, and cerebral ataxia may be seen. Ipsilateral CN deficits (because these nuclei largely reside in the brainstem) occur with contralateral “body” deficits resulting from motor/sensory fiber decussation.

91.3. Headache, vomiting, and a decreased level of consciousness are most commonly seen with which of the following disorders?
A. Ischemic stroke
B. Intracranial hemorrhage
C. Migraine headache
D. Subarachnoid hemorrhage (SAH)
E. Tic douloureux

Answer: D. The incidence of headache is highest by far in patients with SAH. Vomiting and depressed loss of consciousness are also generally more common in this group. Pure migraine headache rarely, if ever, causes a depressed loss of consciousness. Tic headaches do not cause loss of consciousness.

91.4. What percentage of patients with hemorrhagic stroke experience clinical deterioration because of growth in hemorrhage volume within the first hours?
A. 10%
B. 20%
C. 30%
D. 50%
E. 75%

Answer: C. Thirty percent of patients with intracerebral hemorrhage (ICH) experience early hemorrhage expansion. Progression of neurologic deficits and decreasing mental status suggest the diagnosis.

91.5. A 69-year-old male presents with headache, vomiting, aphasia, a right lower facial palsy, and right upper greater than right lower extremity weakness. The symptoms began approximately 4 hours before arrival. Vital signs are temperature 99° C, blood pressure (BP) 180/90 mm Hg, respiratory rate 18 breaths per minute, heart rate 92 beats per minute, and oxygen saturation 96% on room air. Emergent computed tomography (CT) scan shows a left temporal intracerebral hemorrhage (ICH). Soon after presentation, the patient experiences increased vomiting and a diminishing level of consciousness. What is the most likely explanation for this deterioration?
A. Accompanying subarachnoid hemorrhage (SAH)
B. Acute brainstem herniation
C. Hypoxia from neurogenic pulmonary edema
D. Increase in volume of the ICH
E. Myocardial infarction with cardiogenic shock

Answer: D. Approximately one-third of patients with ICH experience early hemorrhage volume expansion. Although brainstem herniation is a possibility, this is typically a later sequelae with a more gradual presentation. Acute myocardial infarction may be associated with intracranial emergencies but would not likely cause an abrupt mental status change. Neurogenic pulmonary edema may accompany any condition with elevated intracranial pressure (ICP) but, again, would not likely cause an abrupt mental status change.

91.6. After complete occlusion of cerebral vessels, irreversible neurologic deficits are expected to reliably occur within how many hours?
A. 2
B. 3
C. 4
D. 5
E. 6

Answer: E. Thus ischemic stroke trials, using fibrinolytic or antiplatelet agents, have attempted to recanalize occluded arteries and reperfuse ischemic areas of the brain within a 2- to 6-hour therapeutic window.

91.7. Which of the following areas of the brain is perfused by the posterior circulation?
A. Internal capsule
B. Posterior aspect of the temporal lobe
C. Putamen
D. Speech areas of the temporal lobe
E. Thalamus

Answer: E. The thalamus is perfused by the posterior circulation. The other areas are perfused by the anterior circulation.

91.8. Which of the following statements regarding stroke etiology is true?
A. Lacunar strokes reliably cause a pure motor deficit.
B. Less than 1% of strokes occur in the 15- to 45-year-old age group.
C. One-third of ischemic strokes are thrombotic.
D. Strokes resulting from atrial fibrillation likely involve small vessels.
E. Two-thirds of ischemic strokes are cardioembolic.

Answer: C. One-third of ischemic strokes are thrombotic. Lacunar strokes may cause a pure motor, pure sensory, or ataxic/hemiparesis stroke. Vessel occlusion resulting from atrial fibrillation–induced emboli more likely involves the large vessels. Three percent to 4% of ischemic strokes occur in the 15- to 45-year-old age group.

91.9. A 29-year-old female presents with a left-sided headache after a moderate-speed motor vehicle collision (MVC). She suffered no loss of consciousness and has no other complaints or obvious injuries. Physical examination is remarkable only for drooping of the left eyelid and slight miosis of the left pupil compared with the right. Which of the following would be the diagnostic test of choice?
A. Brain magnetic resonance imaging (MRI) with gadolinium
B. Contrast computed tomography (CT) scan of the brain
C. CT angiogram of the carotid arteries
D. Uncontrasted CT scan of the brain
E. Urine drug screen

Answer: C. Carotid or vertebral artery dissection can occur after trauma or mild events, such as yoga, twisting, or prolonged static positions looking upward. The hallmark is unilateral neck pain, face pain, or headache, often with accompanying Horner’s syndrome. Acutely, cerebral ischemic changes would not be seen on brain imaging. Carotid and vertebral dissection is not a contraindication for thrombolytic therapy in the eligible patient.

91.10. What percentage of patients who experience a transient ischemic attack (TIA) will develop a stroke within 3 months?
A. 5%
B. 10%
C. 15%
D. 20%
E. 25%

Answer: B. One-tenth of them will occur within 2 days of the sentinel event.
91.11. A 28-year-old G3P3 woman who is 2-weeks postpartum after an uncomplicated vaginal delivery presents with acute onset of mild headache, lethargy, and double vision. Physical examination is remarkable for normal vital signs and a left eye lateral gaze palsy. The most appropriate intervention is likely to be which of the following?  
A. Computed tomography (CT) scan of the brain with possible lumbar puncture  
B. CT scan of the brain and intravenous (IV) heparin  
C. Erythrocyte sedimentation rate (ESR) and IV corticosteroids  
D. IV magnesium  
E. Lumbar puncture and IV antibiotics  

Answer: B. Cerebral venous thrombosis may present with headache, lethargy, cranial nerve (CN) deficits, seizures, or even psychiatric complaints. CT scan and/or magnetic resonance imaging (MRI)/magnetic resonance angiography (MRA) are likely to reveal the diagnosis. Treatment includes heparin. Neurosurgical consultation is not useful. Subarachnoid hemorrhage (SAH) would not be expected to cause a focal neurologic deficit. Eclampsia and meningitis would be expected to give characteristic findings on history and examination.

91.12. Which of the following statements is true regarding management of acute ischemic stroke?  
A. Heparin is indicated for patients in whom thrombolysis is not an option.  
B. If the initial computed tomography (CT) scan shows a large left middle cerebral artery (MCA) distribution stroke but no hemorrhage, thrombolysis would be indicated.  
C. Initial blood pressure (BP) greater than 185/110 mm Hg would contraindicate thrombolytic treatment.  
D. Mechanical thrombectomy may be indicated up to 6 hours after stroke onset.  
E. No clot retrieval devices have been U.S. Food and Drug Administration (FDA) approved for acute ischemic stroke management.  

Answer: D. Intra-arterial thrombolysis may offer benefit up to 6 hours past stroke onset. BPs higher than 185/110 mm Hg are not an absolute contraindication to thrombolysis if they can be lowered to this level with one or two doses of a parenteral agent, such as labetalol or enalapril. The Mechanical Embolus Removal in Cerebral Ischemia (MERCI) retrieval device was FDA approved in 2004, and several newer stent-retriever devices have been approved since then. In recent trials of thrombectomy, improved outcomes were demonstrated at least to 6 hours; and outcomes were even better when patients received reperfusion within 4.5 hours of onset. Aspirin has a proven benefit in patients who do not receive tissue plasminogen activator (tPA). There is no proven benefit to heparin, although some practitioners use it in cases at high risk of stroke progression.

91.13. An 82-year-old male presents with an apparent stroke. He is rapidly evaluated and determined to be within the 3- to 4.5-hour window for fibrinolytic therapy. Which of the following exclusion criteria applies only to the 3- to 4.5-hour criteria and not the 0- to 3-hour criteria?  
A. Administration of heparin within the 48 hours preceding the stroke onset  
B. Age older than 80 years  
C. High clinical suspicion for subarachnoid hemorrhage (SAH)  
D. Seizure at the onset of the stroke  
E. Symptoms rapidly improving  

Answer: B. In the 3- to 4.5-hour window, patients cannot exceed 80 years of age. Heparin administration within the 48 hours preceding stroke onset is a contraindication in both the 0- to 3-hour window as well as the 3- to 4.5-hour window. Similarly, high clinical suspicion for SAH, seizure at the onset of the stroke symptoms, and rapidly improving symptoms are contraindications to fibrinolysis in both time windows.

91.14. A 66-year-old female presents with a possible transient ischemic attack (TIA). Approximately 1 hour before her arrival, she had a 15-minute episode of strictly right arm and right leg weakness, and her symptoms have now resolved. Her blood pressure (BP) is 165/92 mm Hg. Her prior medical history is significant for hypertension, high cholesterol, and diabetes mellitus. What is her ABCD2 score?  
A. 4  
B. 5  
C. 6  
D. 7  
E. 8  

Answer: C. The patient’s ABCD2 score is 6 (age >60 years, BP >140/90 mm Hg, unilateral weakness, symptoms lasting 10 to 59 minutes, and history of diabetes). No speech impairment is reported.

91.15. A 72-year-old male presents with an apparent stroke. Computed tomography (CT) imaging of the brain demonstrates only a hyperdense middle cerebral artery (MCA) sign and no other ischemic changes. He was last seen neurologically normal 4 hours earlier. Which of the following is a contraindication to fibrinolytic therapy in this patient?  
A. His blood glucose is 372 mg/dL.  
B. His National Institutes of Health (NIH) Stroke Scale score is 24.  
C. His platelet count is 110,000/mm³.  
D. His systolic blood pressure (BP) is 180 mm Hg.  
E. He takes warfarin daily.  

Answer: A. Any oral anticoagulant treatment (regardless of the patient’s international normalized ratio [INR]) is a contraindication to fibrinolysis in the 3- to 4.5-hour treatment window. Other contraindications include an NIH stroke scale score greater than 25, platelet count less than 100,000/mm³, blood glucose greater than 400 mg/dL, and systolic BP greater than 185 mm Hg.

91.16. A 75-year-old man is brought to the emergency department (ED) for altered mental status. After computed tomography (CT) imaging of the brain is performed, he is found to have a large intracerebral hemorrhage (ICH). Which of the following options is not an appropriate strategy for lowering intracranial pressure (ICP)?  
A. Barbiturate-induced coma  
B. Hyperthermia induction  
C. Hypertonic saline administration  
D. Hyperventilation  
E. Mannitol administration  

Answer: B. Hypothermia is an experimental modality for lower ICP. Hyperventilation can serve as a temporizing measure for reducing ICP. Mannitol and/or hypertonic saline can also be administered. Inducing a barbiturate coma is also an experimental modality.
CHAPTER 92

Seizures

Elaine Rabin | Andy S. Jagoda

PRINCIPLES

Background and Classification

Seizures are excessive abnormal neuron activity associated with alterations in sensory, motor, autonomic, and/or cognitive function. Convulsion refers specifically to the motor manifestations of a seizure. The ictal period is the time during which a seizure or seizure-like activity occurs. A postictal period is an interval of altered mental status immediately following a seizure, generally lasting less than 1 hour.

Seizures may be provoked by, or secondary to, an acute clinical process (e.g., acute central nervous system [CNS] insults, toxins, and acute metabolic derangements) (Box 92.1). Conversely, primary seizures are unprovoked and have no acute inciting pathology.

Epilepsy refers to a condition of recurrent unprovoked seizures. For example, a patient who suffers head trauma might have a seizure but would not be considered to have epilepsy unless there are recurrent unprovoked ictal events as a result of the brain injury. Many cases of epilepsy are idiopathic, and the onset of these typically occurs during childhood or adolescence. Unprovoked seizures may begin de novo in adulthood, but this is rare and thus a diagnosis of exclusion.

Unprovoked seizures may recur randomly or predictably. Cyclic recurrence has been reported with awakening, sleep deprivation, emotional or physical stress, and menses. A specific sensory stimulus, such as flashing lights or a specific smell, may trigger seizures in certain patients. Note that seizures are still considered “unprovoked” when they are triggered by a process that would not cause a seizure in the nonepileptic patient.

Seizures are classified as partial (focal) or generalized (Fig. 92.1). Partial seizures involve abnormal neuronal firing within a confined population of neurons in one brain hemisphere, and the clinical manifestations tend to reflect the area of electrical activity. Simple focal seizure traditionally refers to focal seizure with preserved mental status, whereas complex focal seizures involve some degree of impaired consciousness. Generalized seizure denotes abnormal neuronal firing throughout both brain hemispheres and always involves alterations of consciousness. Secondarily generalized seizures start as a focal seizure and then progress to a generalized event.

Subclassification of focal seizures, although no longer used, is clinically useful to describe the ictal origin and manifestation. Symptom can be motor (such as, facial twitching or rhythmic ipsilateral extremity movements), autonomic (such as, tachycardia or diaphoresis), somatosensory (such as, tingling or perceiving a certain smell), or psychic (such as, sense of déjà-vu). Psychotic and somatosensory seizures, which involve only subjective, non-observable symptoms, are referred to as auras when they precede a generalized seizure.

The symptoms of generalized seizures are more global. One subtype, absence seizures, manifest as brief dissociative states, often without muscle or postural changes. Other generalized seizures are classified by their specific type of motor activity: tonic (stiffening), clonic (rhythmic jerking), tonic-clonic, myoclonic (discrete violent muscle contractions), or atonic (loss of muscle tone). The common term grand mal seizure refers to generalized tonic-clonic seizures.

Status epilepticus is unremitting seizure activity of greater than 5 minutes’ duration, or recurrent seizure activity without intervening return to baseline mental status. Previous definitions of status epilepticus required 30 minutes of continuous activity based on the time thought to be required for seizures to inflict secondary damage. However, secondary effects can occur in under 30 minutes, and seizure activity is unlikely to cease spontaneously once it has continued for 5 minutes.

Status epilepticus is divided into two basic categories: generalized convulsive status epilepticus (GCSE) and nonconvulsive status epilepticus (NCSE). GCSE typically involves tonic-clonic seizures and is a medical emergency, with mortality directly correlated with the duration of the event. NCSE presents clinically as an alteration in behavior that is associated with continuous epileptiform discharges on electroencephalogram (EEG). The altered mental status may range from a subtle change to coma, and it may be associated with subtle motor signs, such as twitching, blinking, eye deviation, persistent aphasia, or somatosensory findings. NCSE should be considered in patients in coma of undetermined etiology and patients who appear to have a prolonged post-ictal event. NCSE may be present in 10% or more of hospitalized patients with prolonged decreased cognition of undetermined etiology.

A patient is considered to be in refractory status epilepticus when the seizure does not terminate after treatment with a benzodiazepine and a second antiepileptic drug. See Chapter 15 for a detailed discussion of the management of status epilepticus.

A relevant question for the emergency clinician treating the seizing patient is whether the number or duration of seizures carries any significance with regard to the potential for recurrence and how this might influence cognitive outcomes. Patients with provoked seizures show equal incidence of later development of epilepsy regardless of whether or not treatment with antiepileptic drugs was initiated immediately after the inciting event. For patients with unprovoked seizures, the evidence is less straightforward.

Whether recurrent or prolonged seizure activity can lead to cognitive deterioration remains a subject of debate. In general, current data challenge the idea of a common seizure-dependent mechanism for epilepsy progression and intellectual impairment. Although some studies have proposed that status epilepticus alone may result in cognitive impairment, independent of the inciting cause, most recent studies demonstrate that the majority of patients with epilepsy do not show a progressive disorder. The rare cases of intellectual decline and progressive worsening of seizures are limited to specific epileptic events (e.g., mesial temporal lobe epilepsy, which can follow a progressive course induced by recurrent seizure activity).

Epidemiology

Patients presenting to the emergency department (ED) with seizures have a bimodal distribution, with the highest incidence
**BOX 92.1**

**Etiology of Status Epilepticus: Common Causative Disorders**

**METABOLIC DISTURBANCES**
- Hepatic encephalopathy
- Hypocalcemia
- Hypoglycemia or hyperglycemia

**Fig. 92.1.** Simplified classification of seizures. (From ILAE proposal for revised terminology for organization of seizures and epilepsies 2010. Available at: www.ilae.org/commission/class/documents/ILAE%20HandoutV10.pdf.)
Pathophysiology

When normal neurophysiology exists, neuronal cell membranes are stabilized by electrochemical gradients across the membranes and by equilibrium among inhibitory neurotransmitters, such as gamma-aminobutyric acid (GABA), and excitatory neurotransmitters, including glutamate and acetylcholine. Seizures start when the equilibrium across the cell membrane is disturbed, leading to abnormal electrical discharge of cortical and subcortical neurons.

Infection, toxins, electrolyte imbalances, and other pathologic processes can disrupt the neuronal equilibrium locally and trigger electrical activity, resulting in a seizure. Electrical activity, in turn, can lead to recruitment of nearby neurons, and a partial seizure can spread. This is the underlying mechanism for Jacksonian March, when focal motor seizure symptoms spread in a step-wise fashion.

When the electrical activity extends below the cortex to deeper structures, the reticular activating system in the brainstem may be affected, altering consciousness. In generalized seizures, the focus often is subcortical and midline, which likely explains the prompt loss of consciousness and bilateral involvement.

Typically seizures are self-limited; at some point, the hyperpolarization subsides and the electrical discharges from the focus terminate. This termination may be related to reflex inhibition, loss of synchrony, neuronal exhaustion, or alteration of the local balance of acetylcholine and GABA in favor of inhibition. Most drugs used to interrupt seizures act on GABA_\alpha subtype receptors, therefore enhancing inhibitory activity.

During ongoing seizure activity, neuronal GABA_\alpha receptors may be degraded and internalized whereas excitatory N-methyl-D-aspartate (NMDA) receptors may be upregulated. This perpetuates an excitatory state and leads to sustained seizure activity, making it the physiologic basis for the old adage, “seizures beget seizures.” Loss of GABA_\alpha receptors in status epilepticus can decrease response to GABAergic drugs, such as benzodiazepines, barbiturates, and propofol.

Seizures produce a number of secondary physiologic derangements. Sympathetic stimulation leads to increases in body temperature, heart rate, respiratory rate, serum glucose, and lactic acid. Elevated lactate occurs within 60 seconds of a convulsive event and normalizes within an hour after ictus. A rise in the peripheral white blood cell count without an increase in bands is also often seen. With more prolonged convulsions, hypoglycemia, neurogenic pulmonary edema, skeletal muscle damage, and, rarely, frank rhabdomyolysis may ensue. Autonomic discharge and bulbar muscle involvement may result in urinary or fecal incontinence, vomiting, tongue biting, and potential airway impairment. Also rarely, the force generated by the muscle contractions in these seizures can be strong enough to cause posterior shoulder dislocations or fractures.

Clinical History

The clinician should obtain any history of trauma (either before or during the seizure), alcohol intoxication or abuse, and pregnancy. See the Special Cases section for separate discussions of seizures in these contexts.

Although febrile seizures are common in children (see separate discussion of seizures in pediatric patients in Chapter 174) this is not true of adults, and fever preceding a seizure can indicate CNS infection. Patients who are immunocompromised, had recent neurosurgery, or have CNS hardware (such as, a shunt) are at particularly high risk. Fifteen percent of patients with bacterial meningitis will have at least one seizure, and surviving patients have an increased residual risk of epilepsy.

Severe headache prior to a seizure raises concern for intracranial bleeding, especially in elders and anticoagulated patients. Patients with indwelling shunts and a headache prior to seizure may have shunt failure. Headache after a seizure may be indicative of bleeding but may also be part of a post-ictal syndrome.

Seizure patients with preceding neurologic deficits may have a seizure as a symptom of an acute stroke. Ischemic or hemorrhagic stroke is a leading cause of new-onset seizures in elders. The overall incidence of seizures with stroke ranges from 5% to 15%; more than one-half occur within the first week after stroke. The incidence of epilepsy after stroke is 4% to 9%. Seizures that occur acutely with stroke are thought to result from local metabolic alterations in the CNS. These events are transient, and the seizures often are focal and self-limited. Stroke-related seizures that develop later are more likely to be generalized.

Symptomatic dysrhythmias can cause cerebral hypoperfusion and hypoxia, which can lead to seizure activity. Prolonged QT syndrome has been misdiagnosed as a primary seizure disorder. A careful history may identify preceding cardiac symptoms, such as chest pain, palpitations, and syncope.
hemiparesis. Todd’s paralysis is associated with a high likelihood of presenting ranges from weakness of one extremity to a complete hemiparesis. The physician must rule out a new structural lesion. Suspected Todd paralysis that does not quickly resolve, the physician should consider the possibility of a drug-related seizure, which may make a significant difference in management.

An accurate set of vital signs is the foundation of any physical examination. If the patient presents actively seizing, observe the specifics of the motor activity. Focal abnormalities and eye deviation are signs of an epileptic focus. Anecdotally, pupils are often reported to be dilated during or after a seizure; persistent mydriasis may reflect anticholinergic or sympathomimetic toxicity. Some patients in the immediate postictal period. Neurologic deficits may represent an epileptic focus. Anecdotally, pupils are often reported to be dilated during or after a seizure; persistent mydriasis may reflect anticholinergic or sympathomimetic toxicity. Some patients in the immediate postictal period.

A thorough neurologic examination is the key component of the evaluation. Hyperreflexia and extensor plantar responses are suggestive of a recent seizure and should resolve during the immediate postictal period. Neurologic deficits may represent an old lesion, new intracranial pathology, or postictal (Todd’s) paralysis. Todd’s paralysis is a focal motor deficit that may persist up to 24 hours after generalized or complex partial seizures and may be caused by transient focal cerebral hypoperfusion. Clinical presentation ranges from weakness of one extremity to a complete hemiparesis. Todd’s paralysis is associated with a high likelihood of an underlying structural cause for the seizure. In the case of suspected Todd paralysis that does not quickly resolve, the physician must rule out a new structural lesion.

Seizures are often associated with injury, and the patient must be evaluated for both soft-tissue and skeletal trauma. Head trauma and tongue lacerations are common. Seizure activity can also produce dislocations and fractures. Posterior shoulder dislocations are extremely rare but, when present, should prompt suspicion that a seizure has occurred. Seizure-induced fractures are also rare but commonly missed; the humerus, thoracic spine, and femur are most commonly involved.

**Differential Diagnosis**

**Convulsive Syncope**

Syncope associated with seizure-like movements, *convulsive syncope*, is most commonly associated with bradycardia. In these cases, as heart rate returns to normal, abnormal muscle activity ceases, and there is no post-ictal period. Based on observational studies in blood donors, up to 40% of patients with syncope will have some component of motor activity, most commonly involving tonic extension of the trunk or myoclonic jerks of the extremities. This phenomenon has been observed in patients who are in a seated position. These events are usually not associated with tonic-clonic movements, tongue biting, cyanosis, incontinence, or postictal confusion. Nausea or sweating before the event makes seizure much less likely than syncope.

**Nonpaleptic Attacks**

Also referred to as *nonepileptic spells*, these are nonepileptic paroxysmal neurologic events that may resemble seizures in appearance but do not result from abnormal cortical discharge. Etiologies for these include breath-holding spells, involuntary movements, decerebrate or decorticate posturing, and psychogenic seizures. Psychogenic seizures (also known as *pseudoseizures* or *nonepileptic seizures*) have been reported in 12% to 18% of patients with syncope with transient loss of consciousness and can exist concomitantly with neurogenic seizures. Psychogenic seizures are rarely caused by malingering but instead are more commonly a functional neurologic symptom disorder, formerly called a *conversion disorder*. Characteristic features of a psychogenic seizure include out-of-phase tonic-clonic activity, forward pelvic thrusting, and voluntary eye movements away from the examiner.

**Diagnostic Testing**

**Laboratory Studies**

If a patient with a new-onset seizure has no significant comorbid disease and a normal examination (including mental status), the

**Box 92.2**

**Differential Diagnosis of Altered Mental Status in the Patient Who Has Seized**

**POSTICTAL PERIOD**

NCSE or subtle convulsive status epilepticus (can mimic the following):

- Hypoglycemia
- CNS infection
- CNS vascular event
- Drug toxicity
- Psychiatric disorder
- Metabolic encephalopathy
- Migraine
- Transient global amnesia

CNS, Central nervous system; NCSE, nonconvulsive status epilepticus.

Seizures are often associated with injury, and the patient must be evaluated for both soft-tissue and skeletal trauma. Head trauma and tongue lacerations are common. Seizure activity can also produce dislocations and fractures. Posterior shoulder dislocations are extremely rare but, when present, should prompt suspicion that a seizure has occurred. Seizure-induced fractures are also rare but commonly missed; the humerus, thoracic spine, and femur are most commonly involved.

**Nonepileptic Attacks**

Also referred to as *nonepileptic spells*, these are nonepileptic paroxysmal neurologic events that may resemble seizures in appearance but do not result from abnormal cortical discharge. Etiologies for these include breath-holding spells, involuntary movements, decerebrate or decorticate posturing, and psychogenic seizures.

Psychogenic seizures (also known as *pseudoseizures* or *nonepileptic seizures*) have been reported in 12% to 18% of patients with syncope with transient loss of consciousness and can exist concomitantly with neurogenic seizures. Psychogenic seizures are rarely caused by malingering but instead are more commonly a functional neurologic symptom disorder, formerly called a *conversion disorder*. Characteristic features of a psychogenic seizure include out-of-phase tonic-clonic activity, forward pelvic thrusting, and voluntary eye movements away from the examiner.

**Diagnostic Testing**

**Laboratory Studies**

If a patient with a new-onset seizure has no significant comorbid disease and a normal examination (including mental status), the
likelihood of an electrolyte disorder is extremely low. The American College of Emergency Physicians (ACEP) published an evidence-based clinical policy on the initial approach to patients presenting with seizures in 2014. The guidelines emphasize that extensive metabolic testing in patients who had returned to a normal baseline after a first-time seizure is not indicated.12 Also, only a serum glucose and sodium level, as well as a pregnancy test (in women of childbearing age), are likely necessary in patients who are otherwise healthy with a new-onset seizure and normal neurologic status. This is the same conclusion reached in a practice parameter published in 2007 by the American Academy of Neurology on the evaluation of first-time seizures.

Patients with persistent alteration of mental status, those in status epilepticus, and those who have fever or new neurologic deficit are unique in that they require extensive diagnostic testing. This includes serum glucose, electrolytes, urea nitrogen, creatinine, magnesium, calcium, complete blood count, pregnancy tests in women of childbearing age, antiepileptic drug levels, liver function tests, and drugs-of-abuse screening.

Hypoglycemia is a common metabolic cause of provoked seizures. Ictal activity can occur at a plasma glucose level less than 45 mg/dL, although some patients may have a seizure at higher levels. Convulsive and nonconvulsive generalized seizures and focal seizures all may occur during hypoglycemia. Note that prolonged seizures can cause hypoglycemia. Seizures that do not cease after correction of low blood glucose deserve further evaluation and treatment for alternative causes.

If an arterial blood gas analysis is obtained in a convulsing patient (although it is not routinely indicated), it may show an anion gap metabolic acidosis secondary to lactic acidosis. The anion gap acidosis should resolve within an hour after the seizure ends. Persistence beyond this time suggests an underlying process, such as sepsis, ketosis (alcoholic or diabetic), or poisoning (methanol, iron, isoniazid, ethylene glycol, salicylates, carbon monoxide, or cyanide).

A drug-of-abuse screen and alcohol level should be considered in patients with first-time seizures, although there is no evidence that such testing changes outcome. A positive drug-of-abuse screen does not prove causation, and the patient would still require an EEG and neuroimaging study to direct management. The screen may, however, suggest an etiology and help with future medical and psychiatric disposition. Seizure due to alcohol intoxication or withdrawal is a diagnosis of exclusion, because alcoholics are at increased risk for electrolyte abnormalities and traumatic injuries.

Both creatine phosphokinase and prolactin have been investigated as markers of seizures. Neither has been found sufficiently sensitive or specific to be used in the ED.

**Electrocardiogram**

Patients with a history of cardiac disease, preceding or ongoing cardiac symptoms, and those who continue to seize may benefit from cardiac monitoring. The same is true of patients suspected of overdose. An ECG is also an early screen for drug toxicity. Tricyclic cardiotoxicity may manifest as a QRS complex lasting more than 0.1 second or a rightward shift of the terminal 40 ms of the frontal plane QRS complex (a prominent R wave in lead aV6). The ECG can also identify a prolonged QT, a delta wave, Brugada pattern, or heart block, which might contribute further insight into the seizure etiology.

**Neuroimaging**

There is general agreement that neuroimaging is indicated in patients with a first-time nonfebrile seizure, though in select patients who have returned to a normal baseline and who have access to follow up care, imaging can be obtained as an outpatient. The Academy of Neurology guidelines reinforce this, as do studies suggesting that computed tomography (CT) will change acute management of patients with a new seizure in up to 17% of cases.13,14 The usefulness of emergent imaging otherwise depends on the clinical situation. Box 92.3 summarizes useful criteria in determining who will benefit from a CT scan while in the ED.

Magnetic resonance imaging (MRI) is generally the diagnostic test preferred by neurologists in evaluating first-time seizure, because it is better than CT in identifying small lesions. MRI is not better than CT for detecting acute hemorrhage, however, and there are no ED-based studies that have evaluated MRI utility in seizure management.

**Lumbar Puncture**

Lumbar puncture should be considered in patients with fever, severe headache, or persistent altered mental status. Asymptomatic patients with a history or strong suspicion of immunocompromise are also candidates for a lumbar puncture. There are no cases in the literature of a bacterial CNS infection presenting as isolated seizure without fever or abnormal neurologic findings in immunocompetent individuals. Theoretically, an exception may occur in cases of partially treated meningitis.

A transient cerebrospinal fluid (CSF) pleocytosis of up to 20 white blood cells/mm³ has been reported in up to 23% of patients with seizures. However, one is obligated to assume that the presence of white blood cells in the CSF of a seizing patient represents meningitis until proven otherwise.

**Electroencephalogram**

The EEG is the definitive test for diagnosing a seizure disorder, although its sensitivity varies depending on timing and location of the seizure focus. It is particularly helpful when the diagnosis is in doubt, such as in acute confusion states and coma, as well as for the diagnosis of NCSE.13 NCSE has been identified in up to 25% of patients treated for GCSE who were thought to no longer be seizing. Delay in diagnosis of NCSE is associated with increased mortality.13

**MANAGEMENT**

For the patient who has had a seizure prior to hospital arrival or in the ED but is not actively convulsing, only supportive care may be needed. Restraints may be needed during post-ictal confusion to prevent falls, especially in Todd’s paralysis patients who have motor weakness in addition to confusion. However, the use of

Initiation of Antiepileptic Drugs

First-Time Seizures

Based on the best available evidence, the current ACEP Clinical Policy states that emergency clinicians do not need to initiate an antiepileptic drug in patients who have had a first provoked or a first unprovoked seizure without evidence of brain disease or injury. Rather, the patient should be discharged with referral for neurologic consultation. The rationale for this approach is three-fold. First, the diagnosis may be incorrect, especially if the seizure-like activity was not witnessed by experienced medical personnel. It is estimated that 20% to 25% of patients diagnosed as having seizures are eventually determined not to have seizures, with the most frequent alternative diagnoses being cardiovascular and psychopathologic etiologies.

Second, the patient may not have a recurrent seizure. It is estimated that less than 50% of patients who have had a single unprovoked seizure will experience a recurrent seizure within 2 years. The presence of EEG abnormalities suggests greater risk, but this information usually is unavailable in the ED setting. Other factors associated with an increased risk of recurrence are focal (versus generalized) ictus, status epilepticus, a history of intracranial surgery or trauma, and the presence of a persistent neurologic abnormality, such as Todd’s paralysis. Furthermore, whereas treatment decreases the risk of early recurrent seizure, it does not affect long-term prognosis of epilepsy, nor does it have an impact on patient quality of life, with the exception of driving limitations.

Third, antiepileptic medications have side effects that may outweigh the benefit of treatment, especially in women of child-bearing age (owing to their teratogenicity); in patients with liver, kidney, or hematologic disorders; and in patients already taking multiple medications. (The American Academy of Neurology’s evidence-based guideline notes that these are usually mild and reversible.)

For patients with a history of stroke, brain trauma, tumor, or other CNS disease or injury, the ACEP guideline states that antiepileptic drug therapy may be initiated but advises that it is best done by a neurologist in coordination with the patient’s primary care provider. The reason for beginning antiepileptic drugs in this group of patients is their higher probability of recurrence. See Table 92.2 for antiepileptic drug dosing.

Patients With a History of Seizures

Antiepileptic drug noncompliance and subtherapeutic antiepileptic drug levels in a patient who has had a seizure are commonly encountered in the ED. Serum antiepileptic drug levels should be checked in these patients when possible, and repleted if found to be low. Literature to support the recommendation of one route of antiepileptic drug administration over another (oral versus parenteral) is inconclusive, mainly because most available studies used antiepileptic drug serum concentration levels instead of early seizure recurrence as a primary outcome measure. Within this
limited evidence, most studies have compared phenytoin and fosphenytoin in oral and IV routes. Oral loading has been reported to have fewer adverse drug events (eg, hypotension) than either of the IV loading methods. As expected, therapeutic plasma concentrations are achieved significantly faster with the IV route. Some emergency clinicians still prefer parenteral loading of phenytoin or fosphenytoin to ensure adequate serum level on discharge. However, there is no good evidence that this practice decreases risk of seizure recurrence.

**SPECIAL CASES**

**Alcohol-Related Seizures**

Of seizure patients presenting to an ED, 20% to 40% have seizures related to alcohol abuse. Alcohol-withdrawal seizures account for a substantial portion of these alcohol-related seizures, but alcohol abuse and dependence puts patients at risk of seizure in a plethora of other ways, such as increased incidence of traumatic brain injury, hypomagnesemia due to malnutrition, and possible co-ingestion of other toxins. In more than 50% of cases, alcohol-related seizures occur as an adjunct to other risk factors, including preexisting epilepsy, structural brain lesions, and the use of recreational drugs.

A first-time “withdrawal” seizure must be evaluated as any first-time seizure, even in alcoholics who claim to have had seizures in the past but for whom no documentation of previous seizures or evaluation is available. Other conditions need to be ruled out by history, physical examination, and diagnostic testing, including electrolytes, glucose, and brain CT scan.

The diagnostic yield for CT following a first alcohol-related seizure is high. A 1988 Denver study reported head CT scan results in 259 patients with a first alcohol-related convulsion. A clinically significant lesion was found in 16 (6.2%) patients, seven of whom were alert and had nonfocal neurologic examinations and no history of trauma. Nearly 4% had CT findings that changed clinical management (eg, subdural hematoma, aneurysm, subarachnoid hemorrhage, and neurocysticercosis). In these patients, the history and physical examination did not predict the CT abnormality. This study highlights the need to strongly consider neuroimaging in this special group of patients.

The diagnosis of alcohol-withdrawal seizure, after exclusion of other etiologies, is based on a history of recurrent events temporally related to stopping or significantly decreasing alcohol intake. Alcohol-withdrawal seizures are usually generalized events and occur between 6 and 48 hours after cessation of drinking. Seizures occur in one-third of these patients.16

Once a diagnosis of alcohol-withdrawal seizure is made, management focuses on patient safety, minimizing the risk for a second withdrawal seizure, and patient education. Recurrent seizures have been reported in 13% to 60% of these patients, with most occurring within 12 hours of onset. Clinical findings cannot predict who is likely to have a recurrent seizure in the ED. The patient may or may not have other signs of alcohol withdrawal (such as, tachycardia, confusion, or tremors) that may indicate a likelihood of developing a seizure.

Benzodiazepines are the treatment of choice in alcohol-withdrawal seizure. They offer cross-tolerance with alcohol by acting at the GABA receptor site and reduce the signs and symptoms of alcohol withdrawal. All benzodiazepines appear to be equally efficacious in terminating an alcohol-withdrawal seizure; however, lorazepam is the only benzodiazepine that has been shown to decrease the incidence of seizure recurrence and decrease the need for hospitalization. The number needed to treat to prevent one further withdrawal seizure at 6 hours is five.

Phenytoin does not have a role in managing pure alcohol-related seizures in the ED.17

**Toxins**

Toxins can alter the brain equilibrium of excitatory and inhibitory neurotransmitters to cause seizures. Many illicit drugs disrupt the equilibrium, including cocaine and other stimulants and narcotics. Tonic-clonic seizures have been reported with use of synthetic cannabinoids (eg, “spice” and “K2”).18 Marijuana, however, is not commonly associated with seizures, and some forms of severe epilepsy may be treated with medical marijuana.19 Seizures occurring after abuse of N-methyl-3,4-methylenedioxymphetamine (MDMA) compounds (eg, “ecstasy” and “Molly”) may be due to

associated hyponatremia and hyperthermia. Seizures can also result from withdrawal from benzodiazepines or barbiturates.

Cases of toxin-induced refractory status epilepticus pose a particular challenge, because the mechanism of status epilepticus may be different from status epilepticus with other causes. Some toxins (eg, isoniazid) cause depletion of GABA neurotransmitter; and because some of the typical pharmacologic agents act by sensitizing the GABA receptor, they are less effective. In these cases, early administration of pyridoxine may be advantageous, because it replenishes GABA in the brain. It is initially dosed at 5 g IV in adults and 70 mg/kg IV in children.

Most drug-induced seizures, particularly those resulting from cocaine and other stimulants, respond best to benzodiazepine therapy. Barbiturates or propofol are also good options. As with alcohol-induced seizures, phenytoin is ineffective for most drug-induced seizures; and in some cases, it may be harmful such as in theophylline or tricyclic overdose. Phenytoin administration is generally contraindicated in cases of ingestion, because its sodium channel blocking actions can worsen the hemodynamic impact of the ingestion.25

Post-Traumatic Seizures

The incidence of seizure after head trauma is related to injury severity. After minor head injury (Glasgow Coma Score [GCS] >12) the incidence is 1.5%, whereas the incidence increases to 17% after a severe traumatic brain injury (GCS <9). The incidence approaches 30% in patients with depressed skull fracture.25 Immediate and early (within 1 week) post-traumatic seizures are more common in children than in adults, and children also are more likely than adults to present in status epilepticus in the immediate or early post-traumatic phase.

The incidence of post-traumatic seizures in the first week after a severe traumatic brain injury decreases to less than 4% with early treatment with phenytoin. However, after the first week there is no statistical difference in seizure incidence whether or not patients are treated with phenytoin. Thus, treatment with 1 week of antiepileptic drugs is recommended in adults and may be considered in children for prophylaxis against post-traumatic seizures. Long-term prophylactic antiepileptic drugs are not indicated to prevent late post-traumatic seizures.

Pregnancy

Seizures in pregnancy can be classified as one of three types: (1) those that occur in epileptic patients who happen to be pregnant, (2) new-onset seizures in pregnant patients, and (3) seizures that occur in the setting of eclampsia.

The most complete prospective observational study of pregnant women with epilepsy is the International Registry of Antiepileptic Drugs and Pregnancy (EURAP). Of 1956 pregnancies, over half were seizure-free, 17.3% had an increase in seizure frequency, and 15.9% had a decrease in frequency.24 Factors that may lower the seizure threshold in women who are pregnant include noncompliance, sleep deprivation, nausea, and vomiting.

Overall, there is no increased risk of status epilepticus during pregnancy.25 Although there are few data guiding the use of antiepileptic drugs for status epilepticus during pregnancy, the risks to the fetus from status epilepticus–related hypoxia and acidosis are greater than the potential teratogenicity of anticonvulsant medications; therefore, patients who are actively seizing should be managed as the nonpregnant patient. In patients who are more than 24 weeks pregnant, fetal monitoring during and after a seizure should be arranged.

Pregnant patients with new-onset seizures (not with eclampsia) should be worked up as any new-onset seizure patient, with a metabolic profile, EEG, and head CT scan with appropriate abdominal shielding. Precipitating etiologies, such as infections and drug toxicities, should also be investigated. If no source is identified, anticonvulsants should be withheld and the patient referred for close follow-up.

Eclampsia is the major consideration in pregnant patients of at least 20 weeks’ gestation who present with new-onset seizures. Postpartum eclampsia represents 25% of eclamptic seizures, can occur up to 8 weeks after delivery, and can be seen in women without preceding preeclampsia.

Magnesium has been demonstrated to be the therapy of choice in the treatment of acute eclamptic seizures and for prevention of recurrent eclamptic seizures. It has been shown to be substantially more effective than phenytoin with regard to recurrence of convulsions and maternal death. Complications including respiratory depression and pneumonia are less likely with magnesium than phenytoin. Magnesium sulfate is also associated with benefits for the baby, including fewer admissions to the neonatal intensive care unit.

In the eclamptic patient, magnesium sulfate 4 g IV should be given over 20 minutes, followed by a 2 g/h infusion (some centers use intramuscular regimens). According to the American College of Obstetrics and Gynecology and the National High Blood Pressure Education Program: Working Group Report on High Blood Pressure in Pregnancy, agents of choice for control of blood pressure in the emergency setting include hydralazine (first-line) and labetalol.26 Eclamptic seizures refractory to magnesium may respond to benzodiazepines or barbiturates with or without phenytoin. An in-depth discussion of eclampsia can be found in Chapter 178.

DISPOSITION

The need for hospitalization is obvious in patients who are clinically ill, but a dilemma arises when determining disposition for the patient who returns to a normal baseline after a first-time seizure. The best predictor of seizure recurrence is the causative etiology combined with EEG findings. This information often requires modalities that are not routinely available in the ED, and there are few ED-based studies to direct disposition. Retrospective studies suggest that there is a 19% seizure recurrence rate within 24 hours of presentation to the ED, which decreases to 9% if patients with alcohol-related events or focal lesions on CT are excluded. However, selection bias in these studies makes it impossible to assess whether recurrence could have been predicted based on physical findings or comorbid factors. Thus, at present, there is insufficient evidence to guide the decision to admit. We recommend this decision be tailored to the patient and shared decision-making be employed, taking into consideration the patient’s access to follow-up care and social risk factors (eg, alcoholism or lack of health insurance). Patients with comorbidities, including older than 60 years old, known cardiovascular disease, history of cancer, or history of immunocompromise, should be considered for admission to the hospital.

Patients and their families should be counseled and instructed on basic safety measures to prevent complications (such as, trauma) during seizures. For example, patients should be advised to avoid swimming or cycling following a seizure, at least until they have been reassessed by their neurologist and their antiepileptic therapy optimized, if needed. The need for a “medical alert” bracelet or other medical condition identifier should be considered.

A particularly important point for seizure patients is education against driving. Although evidence remains controversial on this issue, there is general agreement that uncontrolled epileptic patients who drive are at risk for a motor vehicle collision, with potential injury or death to themselves and others. For this reason, most states do not allow these patients to drive unless they have
been seizure-free on medications for 1 year. According to population survey data, 0.01% to 0.1% of all motor vehicle crashes are attributable to seizures. Although physicians are required to report patients with seizures to driving authorities in six states (California, Delaware, Nevada, New Jersey, Oregon, and Pennsylvania), mandatory reporting has not been proven to reduce the risk of motor vehicle crash in patients with epilepsy.

The psychological and social implications of the new diagnosis of a seizure disorder for the patient can be profound. Fear of seizures and stigmatization are common; employability and insurability may be adversely affected. Although the emergency clinician is not usually in a suitable position to arrange for counseling, referral to local epilepsy support groups may be helpful.

**KEY CONCEPTS**

- Seizures can be provoked by many acute processes, including infections, toxins, cardiac dysrhythmias, and CNS insults.
- Epilepsy is a condition of recurrent, *unprovoked* seizures.
- Partial seizures are confined to one hemisphere of the brain and have clinical manifestations reflecting the area of electrical activity. Generalized seizures involve both hemispheres and always involve alterations in consciousness.
- There is no single test to confirm that a patient seized, and a number of seizure mimics including convulsive syncope exist. A post-ictal alteration in mental status makes a seizure five times more likely than syncope.
- Although most seizures are self-limited, management of the seizure patient involves a targeted search for underlying pathology, treatment of sequelae of seizures when necessary, and prevention of future episodes.
- Stroke is a leading cause of new seizure in elders.
- Noncompliance with antiepileptic medication is the most common cause of ED presentation for recurrent seizures.
- During a seizure, the patient should be placed in the left lateral decubitus position when possible. Suctioning may help prevent aspiration, but intraoral devices will cause trauma without yielding significant benefit.
- A patient with new-onset seizures who returns to baseline mental status and does not have comorbid disease does not require diagnostic testing beyond serum glucose and sodium levels, a pregnancy test (in women), and a non-contrast head CT.
- Non-convulsive status epilepticus should be considered in any patient with prolonged, unexplained altered mental status.
- For patients with a first-time seizure and without a clear CNS disease or lesion, evidence does not support initiation of antiepileptic drugs in the ED.
- Alcohol dependence places patients at risk of seizures in a number of ways, and alcohol-withdrawal seizures should only be diagnosed after excluding other causes. These seizures, as well as seizures due to other drugs of abuse, respond to benzodiazepines but not to traditional antiepileptic medications.
- Antiepileptic medications have been shown to reduce post-traumatic seizures in the first week after injury but not beyond that.
- In pregnant patients, evaluations for new-onset seizures prior to 20 weeks should be the same as in nonpregnant patients. After 20 weeks, eclampsia is a major cause of seizures and is treated with magnesium.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Medication noncompliance is the most common cause of recur-
zures. Idiopathic epilepsy almost always starts in childhood.

Which of the following statements regarding epilepsy is 
true? 
A. During a seizure, prompt loss of consciousness implies 
a cortical focus. 
B. Generalized seizures involve abnormal electrical 
activity in one hemisphere. 
C. Regarding seizure activity, acetylcholine is inhibitory. 
D. Regarding seizure activity, gamma-aminobutyric acid 
(GABA) is excitatory. 
E. The clinical seizure activity typically reflects the brain 
focus of initiation.

Answer: E. Clinical seizure activity typically reflects the site 
of seizure origin. Generalized seizures involve both brain hemi-
pheres. Acetylcholine is an excitatory neurotransmitter, and 
GABA is inhibitory. Prompt loss of consciousness with a seizure 
implies a subcortical focus involving the reticular activating 
system.

Which of the following statements regarding epilepsy is 
true? 
A. Electrolyte disturbances are the most common cause of 
recurrent seizures in epileptic patients. 
B. Epilepsy is a condition of recurrent provoked seizures. 
C. Epileptic seizures are always generalized tonic-clonic. 
D. Epileptic seizures can be triggered by smells or lack of 
sleep. 
E. Most adult-onset epilepsy does not have an identifiable 
causal factor.

Answer: D. Epilepsy is a condition of recurrent, unprovoked 
seizures. Idiopathic epilepsy almost always starts in childhood. 
Medication noncompliance is the most common cause of recur-
rent seizures in epileptic patients. Epileptic seizures can be partial 
seizures. Some patients with epilepsy have seizures triggered by 
specific sensory stimuli, with flashing lights being the most 
well-known of these.

Which of the following factors does not put patients at 
risk for seizures? 
A. Acute stroke 
B. Chronic stroke-related lesions 
C. Hyperkalemia 
D. Hypomagnesemia 
E. Indwelling intracranial shunts

Answer: C. Indwelling intracranial shunts and other lesions, 
and hypomagnesemia (as seen in malnourished alcohol-dependent 
patients) are all risk factors for seizures. Stroke is one of the 
most common causes of seizures in the elderly. Seizures occurring 
acutely with a stroke are often partial and reflect the affected brain 
area, whereas those that occur chronically are often generalized. 
Hyperkalemia does not cause seizures unless it precipitates hypo-
tension and consequent hypoperfusion of the brain.

Which of the following statements regarding patients 
presenting with first-time seizures is true? 
A. All patients should have basic serum electrolyte testing. 
B. All patients should receive a loading dose of an 
antiepileptic drug and a prescription for an oral 
regimen prior to discharge. 
C. Non-contrast head computed tomography (CT) is not 
indicated for most afebrile patients. 
D. Non-diabetic patients do not need to have serum 
glucose checked if their mental status returns to 
normal. 
E. Persistent altered mental status is an indication for a 
lumbar puncture.

Answer: E. Persistent altered mental status should trigger consid-
eration of a lumbar puncture, serum glucose and an electroen-
ccephalogram (EEG) among other testing. Non-contrast CT of 
the head is relatively high-yield in first time seizure patients, 
and most guidelines recommend performing one. Patients with 
no comorbidities who return to baseline mental status do not need
broad-based electrolyte testing, but hypoglycemia is a common cause of seizures even in non-diabetic patients and should be routinely tested for in first-time seizure patients. Initiation of antiepileptic drugs in the emergency department (ED) for first-time seizure patients without a known structural brain lesion may do more harm than good.

92.5. Which of the following statements regarding post-traumatic seizures is true?
   A. Adults are more likely to present with status epilepticus.
   B. Antiepileptic drugs are effective in preventing late post-traumatic seizures.
   C. Immediate and early post-traumatic seizures are more common in adults.
   D. Most occur immediately following the traumatic injury.
   E. The severity of head injury correlates with the likelihood of post-traumatic seizures.

Answer: E. The severity of head injury correlates directly with the likelihood of post-traumatic seizures. The incidence of seizures is higher when the dura is violated. Children are more likely to have immediate or early (<1 week) seizures and to present in status. Antiepileptic drugs do not affect the incidence of late post-traumatic seizures (>1 week).

92.6. For which of the following causes of seizure are alcohol-dependent patients not at increased risk?
   A. Electrolyte disturbances
   B. Head trauma
   C. Toxin-induced (other than alcohol)
   D. Uremia
   E. Withdrawal

Answer: D. Alcohol-dependent patients frequently fall or otherwise sustain head trauma during periods of intoxication. Alcohol withdrawal is associated with a high incidence of seizure. Alcohol intoxication can be associated with co-ingestion of illicit drugs, which also cause seizures. Chronic alcohol dependence can be associated with malnutrition causing hypomagnesemia.

92.7. Which of the following regarding seizures from illicit drug use is true?
   A. Benzodiazepines are contraindicated in cessation of these seizures.
   B. K2 (“spice”) has not yet been reported to cause seizures.
   C. Marijuana use is strongly associated with seizures.
   D. N-methyl-3,4-methylenedioxyamphetamine (MDMA) compounds, such as ecstasy, may induce seizures via hyperthermia.
   E. Phenytoin is the first-line treatment.

Answer: D. Seizures from cocaine, MDMA compounds and other drugs are notoriously unresponsive to traditional antiepileptic agents, and benzodiazepines are considered the first line of treatment. Marijuana is generally not associated with seizures, although synthetic cannabinoids, such as K2, have been. Ecstasy and other MDMA compounds inhibit sweating and can cause seizures by inducing hyperthermia.

92.8. A 23-year-old woman is brought to the emergency department (ED) for a prolonged seizure. By emergency medical service (EMS) report, the patient has no past medical history and no history of seizures. Paramedics report tonic-clonic activity for approximately 15 minutes, refractory to diazepam 5 mg intravenously in the ambulance. Upon arrival to the ED, the patient’s seizure activity abruptly ceases, and she lucidly responds to the history and physical examination. She is symptom free. What would be the most appropriate intervention?
   A. A trial of oral phenytoin after an intravenous (IV) loading dose in the ED
   B. Computed tomography (CT) scan of the head followed by lumbar puncture
   C. Confrontation
   D. Neurology referral for electroencephalogram (EEG) and consultation
   E. Psychiatric consultation

Answer: D. No clinical criteria are 100% specific for the diagnosis of pseudoseizures. Seizures and pseudoseizures may coexist. For many patients, these episodes may not be deliberate. The most prudent course of action would be to treat them as possible ictus and refer to a neurologist. Initiation of antiepileptic drugs in the ED is not indicated in first-time seizures of healthy patients who return to normal.
Headache is a common complaint, accounting for approximately 5 million visits to the emergency department (ED) per year in the United States. In addition, many more patients present with headache as part of a constitutional illness, making the symptom of headache one of the most frequent complaints in the ED.

Headache is divided into primary and secondary disorders. **Primary headache disorders** include migraine, cluster, and tension-type headaches, which represent the majority of headaches seen in clinical emergency practice. **Secondary headache disorders** include a variety of organic illnesses in which head pain is a symptom of an identifiable, distinct pathologic process. To facilitate a standardized approach to headache management, the International Headache Society published a classification system and diagnostic criteria for headache disorders, cranial neuralgias, and facial pain. This comprehensive and widely accepted system includes 14 major categories of headache disorders and uses specific operational diagnostic criteria to define each headache type (Box 93.1). Most patients presenting to an ED with headache have a benign primary headache disorder requiring only symptomatic treatment and referral. The challenge for the emergency clinician is to identify the very small subset of patients who have headache as a symptom of a serious or potentially life-threatening disease.

**PRIMARY HEADACHE DISORDERS**

### Migraine Headache

**Principles**

Migraine is a common, chronic, sometimes incapacitating neurovascular disease characterized by recurrent attacks of severe headache, autonomic nervous system dysfunction, and, in some patients, an aura causing visual, sensory, motor, or other neurologic symptoms. It is a primary headache disorder with a genetic basis.

Migraine headaches account for more than 1.2 million visits to the ED per year. Migraine attacks typically begin in the second decade of life and peak in prevalence in the fourth decade, with a 1-year period prevalence of 7% of men and 24% of women. Overall, migraine is more prevalent among women (18%) than among men (6%). During childhood, however, there is no gender difference in the prevalence of migraine. After menopause, the prevalence of migraine among women decreases.

Historically, migraine headaches have been considered to be vascular in origin. However, this hypothesis is no longer tenable as alterations in cerebral blood flow do not correlate with the various phases of the headache attack or vascular territories and do not explain features of an acute migraine, such as premonitory mood disturbances, nausea, and osmophobia. Rather, vascular changes are now thought to be an epiphhenomenon to what is a primary neurologic event. Abnormal trigeminal nerve activation, possibly triggered by cortical spreading depression or, less likely, a sterile neuropeptide-induced inflammatory process, leads to pain and sensitization of higher order neurons in the brainstem and thalamus. Descending modulation is likely to be compromised as well. It is not yet known what initiates the pathophysiologic process that leads to a migraine attack. Migraine is commonly thought of in two major categories: (1) migraine without aura, which is the most frequent form of migraine and accounts for approximately 80% of all cases (Box 93.2); and (2) migraine with aura, which has specific reversible neurologic symptoms that precede the actual headache (Box 93.3) and is seen less frequently.

**Clinical Features**

Migraine is by definition a chronic and recurrent disease. The headache, characteristically, is unilateral, pulsating in quality, moderate to severe in intensity, and exacerbated by routine activities. The side of the headache can vary with individual attacks, and the headache may be bilateral in 40% of patients. The onset usually is gradual, and the attacks typically last 4 to 72 hours. Headache frequency is variable; those patients with more than 15 headache days per month are considered to have chronic migraine. Associated symptoms and signs include nausea, vomiting, anorexia, photophobia, phonophobia, osmophobia (aversion to odors), blurred vision, lightheadness, vertigo, muscle tenderness, and nasal congestion. Many patients have dramatic light and sound sensitivity and seek a cool, dark, and quiet room. Some patients experience premonitory cognitive impairment during the days leading up to the acute attack producing forgetfulness, irritability, and depression.

The migraine aura consists of focal neurologic symptoms that precede and herald the headache. By definition, the aura is fully reversible and typically lasts 10 to 20 minutes, although it may continue for as long as 1 hour. The most common aura is visual; features may include scintillating scotomas (bright rim around an area of visual loss), teichopsia (subjective visual image perceived with eyes open or closed), fortification spectra (zigzagged lines that slowly drift across the visual field), photopsias (poorly formed brief flashes or sparks of light), and blurred vision. Less common auras include somatosensory phenomena, such as tingling or numbness, motor disturbances, and cognitive or language disorders.

**Retinal migraine** is a rare syndrome consisting of recurrent attacks of monocular visual dysfunction, including positive features (such as, scintillations) or negative features (such as, blindness). As with aura, these symptoms are completely reversible.

**Hemiplegic migraine** is characterized by a motor aura consisting of hemiparesis or hemiplegia. The progression of the motor deficit is gradual and in most cases is accompanied by a visual, sensory, or speech disturbance. The neurologic symptoms last up to 60 minutes, followed by headache. Rarely, the motor deficit is persistent, resulting from a true migrainous stroke. A familial version of hemiplegic migraine is associated with genetic channelopathies.

**Migraine with brainstem aura** presents with an aura referable to the brainstem. Common neurologic findings include dysarthria, tinnitus, vertigo, diplopia, and altered level of consciousness.
Migraine may be difficult to distinguish from secondary causes of headache. Other disorders that mimic migraine include aneurysmal subarachnoid hemorrhage (SAH), cerebrovascular disease, space occupying lesions, and idiopathic intracranial hypertension (IIH).

### Diagnostic Testing

Neuroimaging is not necessary for patients with typical recurrent migraine headaches. Neuroimaging should be considered for older or immunocompromised patients with new-onset headaches, headaches associated with unexplained neurologic abnormalities, and headaches with an abrupt onset. Such patients have a higher likelihood of having a secondary cause of headache, such as an intracranial bleed or space occupying lesion. Among patients with an acute migraine headache, laboratory testing should be limited to a pregnancy test for those who are to be treated with medications that may be teratogenic and electrolytes for those patients with marked nausea, anorexia, or vomiting who will require intravenous (IV) fluid hydration.

### Management

The pharmacologic treatment of migraine is divided into abortive therapies, which attempt to limit the intensity and duration of a given episode, and prophylactic therapies, which are intended to decrease the frequency and intensity of attacks. Prophylactic therapy is usually not initiated in an ED. The goals of abortive therapy include rapid pain relief, minimization of headache therapy, and prophylactic therapies, which are intended to limit the intensity and duration of a headache episode, depending on the severity of the attack (Table 93.1). The choice of agents depends on the patient’s previous response to specific therapies, the existence of comorbid conditions, and the presence or absence of nausea or vomiting. Gastric stasis is common during acute migraine attacks and may limit the effectiveness of oral agents.

For mild to moderate attacks, simple analgesics such as acetaminophen or nonsteroidal antiinflammatory drugs (NSAIDs) are often effective. In the presence of nausea or vomiting, the addition of an agent (such as, metoclopramide) enhances the absorption and effectiveness of these medications. Appropriate doses and possible side effects are listed in Table 93.1.

---

**BOX 93.1**

### International Headache Society Classification of Headache

#### PRIMARY HEADACHES

1. Migraine
2. Tension-type headache
3. Cluster headache and trigeminal autonomic cephalalgias
4. Other primary headaches

#### SECONDARY HEADACHES

5. Headache attributed to trauma or injury to the head or neck
6. Headache attributed to cranial or cervical vascular disorder
7. Headache attributed to nonvascular intracranial disorder
8. Headache attributed to a substance or its withdrawal
9. Headache attributed to infection
10. Headache attributed to disorder of homeostasis
11. Headache or facial pain attributed to disorder of cranium, neck, eyes, ears, nose, sinuses, teeth, mouth, or other facial or cranial structures
12. Headache attributed to psychiatric disorder

#### PAINFUL CRANIAL NEUROPATHIES, OTHER FACIAL PAINS, AND OTHER HEADACHES

13. Cranial neuralgias and other facial pain
14. Other headache disorders

**BOX 93.2**

### Migraine Without Aura (Common Migraine): International Headache Society Criteria

A. At least five attacks fulfilling criteria in B, C, D, and E
B. Attack lasts 4 to 72 hours (untreated or unsuccessfully treated)
C. Headache has at least two of the following characteristics:
   1. Unilateral location
   2. Pulsating quality
   3. Moderate to severe pain intensity
   4. Aggravation by or causing avoidance of routine physical activity (eg, walking or climbing stairs)
D. During headache, at least one of the following:
   1. Nausea or vomiting (or both)
   2. Photophobia and phonophobia
E. Not attributable to another disorder

Available at http://ihs-classification.org/en/.

**BOX 93.3**

### Migraine With Aura (Classic Migraine): International Headache Society Criteria

A. At least two attacks that fulfill criterion B
B. Presence of at least three of the following four characteristics for a diagnosis of classic migraine:
   1. One or more fully reversible aura symptoms indicating focal cerebral cortical or brainstem dysfunction (or both)
   2. At least one aura symptom developing gradually over more than 4 minutes, or two or more symptoms occurring in succession
   3. No single aura symptom lasting longer than 60 minutes
   4. Headache beginning during aura or afterward, with a symptom-free interval of less than 60 minutes (also may begin before aura)
C. Exclusion of related organic diseases by means of an appropriate history, physical examination, and neurologic examination with appropriate diagnostic tests

Available at http://ihs-classification.org/en/.
For moderate to severe attacks, three classes of medications can be recommended as initial parenteral therapy: the antiemetic dopamine antagonists, such as metoclopramide, prochlorperazine, and droperidol; migraine-specific agents, such as the triptans and dihydroergotamine (DHE); and parenteral nonsteroidal medications, such as ketorolac.

Dopamine antagonists, such as the neuroleptic prochlorperazine, and the antiemetics, metoclopramide and droperidol, are highly effective as monotherapy for acute migraine attacks. Because of their efficacy, safety, tolerability, and few contraindications, they are often used as first-line therapy for acute migraine. For this class of medication, clinical research has outpaced preclinical work, and thus a compelling mechanism of action is lacking. However, migraine pathogenesis likely involves dopamine pathways. The most common side effects after parenteral administration include sedation, and extrapyramidal symptoms, most notably akathisia, which can be treated with diphenhydramine, 25 mg IV, or midazolam, 2 mg IV.\textsuperscript{10,11}

DHE is administered intravenously in a dosage of 1.0 mg over 2 minutes; this can be repeated in 1 hour if pain control has not been achieved. Because DHE can cause nausea and vomiting, patients should be pretreated with an antiemetic, such as metoclopramide 10 mg IV or prochlorperazine 10 mg IV. Contraindications to use of DHE include pregnancy, breast-feeding, poorly controlled hypertension, coronary artery disease, and peripheral vascular disease. DHE should not be used if the patient has already taken any drug in the triptan class or if the patient is using macrolides or protease inhibitors.

Sumatriptan, the first-approved medication of the triptan class, a class of selective 5-HT (1B/1D) receptor agonists, is available for oral (100 mg) and subcutaneous (6 mg) administration, and it is the most common triptan preparation used in the ED setting.\textsuperscript{3} Other oral triptans include eletriptan (40 mg), almotriptan (12.5 mg), zolmitriptan (2.5 mg), naratriptan (2.5 mg), frovatriptan (2.5 mg), and rizatriptan (10 mg). Common side effects of triptans include tingling, flushing, warm or hot sensations, heaviness in the chest, and initial worsening of the underlying headache. Sumatriptan has contraindications similar to those for DHE and should not be used within hours of administration of an ergotamine-containing medication or DHE. A smaller dose of subcutaneous sumatriptan may limit side effects. Intranasal and rectal triptan preparations do not have a place in ED migraine treatment.

Opioid analgesics (such as, morphine, dosed at 0.1 mg/kg) should be reserved for patients who do not respond to any of the medications listed or have contraindications to all standard migraine therapies. Although hydromorphone and meperidine are frequently used, they are less efficacious than other agents and are associated with frequent ED visits.

Recurrence of migraine within 24 hours of ED discharge is common, regardless of medication administered or pain intensity at discharge.\textsuperscript{12} We recommend using dexamethasone 10 mg IV to

Cluster Headache

Principles

Cluster headache is the only headache syndrome that is more common in men than in women. It typically occurs in young to middle-aged adults who smoke. The headaches tend to occur repeatedly during a defined time interval, hence the term *cluster*. Several attacks can occur in a single day, and a typical cluster period may last weeks to months. Several precipitating factors have been implicated, most notably the ingestion of alcohol. Stress and climate changes may also play a role in susceptible persons. As with migraine, abnormal activation of the trigeminal nerve contributes to headache nociception. Secondary parasympathetic activation causes typical associated symptoms, such as lacrimation and rhinorrhea.

Clinical Features

Cluster headaches occur suddenly with little warning, and multiple episodes can occur within a 24-hour period. Each headache lasts from 15 minutes up to 3 hours. The headache typically begins with a unilateral sharp, stabbing pain in the eye, which may awaken the patient from sleep. The attacks occur exclusively in the territory of the trigeminal nerve. Unlike the migraineur, the patient with cluster headache predictably presents agitated and anxious, rocking, rubbing the head, and pacing. The attack subsides rapidly, often leaving the patient exhausted. Accompanying the headache are ipsilateral autonomic symptoms, such as ptosis, miosis, and forehead or facial sweating. The eye often is injected and tearing, and many patients have unilateral nasal congestion.

Differential Diagnoses

Other headache disorders that mimic cluster headache include carotid artery dissection, trigeminal neuralgia, and rare trigeminal autonomic cephalalgias, including paroxysmal hemi面部 headaches and short-lasting uniform neuralgiform headache attacks with conjunctival injection and tearing (SUNCT). Carotid artery dissection should be excluded as the diagnosis in patients who present with unilateral face or neck pain and Horner’s syndrome. With trigeminal neuralgia, the pain peaks within seconds, lasts only a couple of minutes, and can be provoked by specific trigger points on the face or oral mucosa. The trigeminal autonomic cephalalgias are manifested by a brief unilateral headache that recurs dozens of times per day, often accompanied by the same unilateral eye and nasal symptoms as cluster.

Diagnostic Testing

For patients without an established pattern of cluster headaches, the emergency clinician should consider space-occupying central nervous system (CNS) lesions, which may be hidden in the posterior fossa, and carotid artery pathology. Magnetic resonance imaging (MRI) is required to exclude subtle posterior fossa pathology. If MRI is not available in the ED, we believe a CT scan to exclude obvious lesions followed by outpatient MRI is a reasonable alternative. Neurovascular imaging is required to exclude carotid artery dissection when this diagnosis is suspected.

Management

Cluster headache is brief in duration and may resolve before a patient presents to medical attention. High-flow oxygen is first-line therapy. Delivered through a non-rebreather mask at a rate of 12 L/min, it aborts the headache within 15 minutes in approximately 80% of patients. Subcutaneous sumatriptan is also an effective therapy for acute cluster headache and should be dosed at 6 mg. Larger doses do not confer additional benefit and may contribute to medication side effects. Alternatively, subcutaneous octreotide (100 µg) may be effective.

Once the acute attack has been relieved, focus shifts to the ongoing “cluster” of headaches that likely will recur the following day. Corticosteroids have long been theorized to help break the cluster, although high-quality evidence is not available. We recommend a regimen of 100 mg of prednisone daily for 5 days, followed by a 12-day taper. Verapamil, dosed at 120 mg three times a day, may decrease the frequency of attacks by the end of the first week of therapy and should be considered in all patients with cluster headache discharged from the ED.

Disposition

Patients with cluster headache usually do not require admission to the hospital. Because these headaches are likely to continue over the following days and weeks, the patient should be referred to a physician with expertise in headache management.
Clinical Features

Patients typically complain of a tight, bandlike discomfort around the head that is nonpulsating and dull. They also may experience tightening of the neck muscles. A majority of patients do not seek medical assistance, because the headache usually is mild in intensity and not functionally disabling. On occasion, the discomfort can build up slowly and fluctuate in severity for several days. Unlike in migraine, the headache does not worsen with physical activity, and accompanying symptoms (such as, nausea, vomiting, phonophobia, and photophobia) are unusual. Anxiety and depression may coexist with chronic tension headache, which by definition occurs more than 15 days a month and can be daily and unremitting.

Differential Diagnoses

Tension headache is the least distinct of all of the primary headache disorders, and its diagnosis is based mainly on the absence of features that would suggest another headache diagnosis. The most common disorders mimicking tension headache are migraine, IIH, oromandibular dysfunction, cervical spondylosis, sinus or eye disease, and intracranial masses. Subtle indolent infections (such as, cryptococcal meningitis) should be considered in the immunocompromised.

Diagnostic Testing

Patients who present with a headache similar in quality to previous headaches do not require diagnostic evaluation in the ED. New onset headache with features of tension-type headache requires evaluation in patients 50 years and older, as well as immunocompromised patients. This evaluation can take place in the outpatient setting, where a scheduled MRI offers more sensitivity for a range of pathologies than a non-contrast CT.

Management

For a majority of patients with tension headaches, simple analgesics, such as acetaminophen or a NSAID, are adequate for pain control. Antiemetics such as metoclopramide are more efficacious than NSAIDs among patients with tension-type headache who require parenteral treatment. Opioids are generally not warranted. Acupuncture is an efficacious non-pharmacological therapy. Despite muscle pain and tenderness in many of these patients, spinal manipulation therapy is unlikely to provide a benefit for most patients.

Disposition

Absent comorbidities, patients with tension type headache do not require admission to the hospital. Chronic tension-type headache is difficult to manage; these patients should be referred to clinicians with expertise in headache or pain management.

SECONDARY HEADACHE DISORDERS

Subarachnoid Hemorrhage

Principles

SAH refers to extravasated blood in the subarachnoid space. Presence of the blood activates meningeal nociceptors, leading to diffuse occipital pain along with signs of meningeismus. SAH accounts for up to 10% of all strokes and is the most common cause of sudden death from a stroke.

Approximately 80% of patients with nontraumatic SAH have ruptured saccular aneurysms. Other causes include arteriovenous malformations, cavernous angiomas, mycotic aneurysms, neoplasms, and blood dyscrasias. SAH may be caused secondarily by an intraparenchymal hematoma that dissect’s its way into the subarachnoid space.

The risk for aneurysmal SAH increases with age; most cases occur between 40 and 60 years old. In children and adolescents, aneurysms are uncommon, and when SAH occurs, it usually is secondary to an arteriovenous malformation. It is estimated that 2% of the general population harbor a berry aneurysm, and the risk of rupture may increase with aneurysmal size. Other risk factors associated with SAH include hypertension, smoking, excessive alcohol consumption, and use of sympathomimetic drugs. A familial association of cerebral aneurysms with several diseases has been described, including autosomal dominant polycystic kidney disease, coarctation of the aorta, Marfan syndrome, and Ehlers-Danlos syndrome type IV.

Of all patients presenting to the ED with a primary complaint of headache, less than 1% have SAH. Many patients with SAH die before reaching the hospital; preadmission mortality rates range from 3% to 26%. Median mortality in the United States is 32% with approximately 20% of survivors having significant functional and cognitive deficits.

Clinical Features

The clinical presentation of SAH is one of the most distinctive in medicine. Approximately 80% of patients present with a sudden, cataclysmic thunderclap headache, which often is described as “the worst headache of my life.” In up to 20% of patients, the onset of headache may be associated with exertion, the Valsalva maneuver, or sexual intercourse, but the majority occurs in the absence of strenuous physical activity. The headache of SAH classically peaks in intensity within seconds to minutes. Headaches that take longer to peak in intensity are less likely to be SAH. Associated signs and symptoms include syncope, nausea and vomiting, neck stiffness, photophobia, and seizures.

Physical findings depend on the extent of the SAH. Meningismus is present in more than 50% of patients, and up to 20% have focal neurologic abnormalities. Funduscopic examination may reveal retinal or subhyaloid hemorrhages, and patients also may have isolated third or sixth nerve palsies. Oculomotor (third) nerve compression secondary to an expanding posterior communicating artery aneurysm leads to pupillary dilation. Approximately 50% of patients with a ruptured aneurysm are restless or have an altered level of consciousness. Up to one-third of patients recall a sentinel headache days to weeks before diagnosis of subarachnoid hemorrhage.

The patient’s prognosis is related to neurologic status at hospital admission. The Hunt and Hess scale stratifies patients according to their clinical signs and symptoms at the time of presentation and is predictive of outcome. Patients who present with a grade 1 or grade 2 hemorrhage tend to have a good prognosis. Patients with grade 4 or 5 hemorrhages tend to do poorly, presenting with an altered mental status, ranging from stupor to deep coma, together with focal neurologic signs and symptoms. Patients with grade 3 hemorrhage present with drowsiness or confusion and are at risk for rapid clinical deterioration.

Differential Diagnoses

Several clinical entities can mimic the abrupt onset headache associated with SAH. These include cerebral artery dissection (CAD), cerebral venous thrombosis (CVT), reversible cerebral vasconstriction syndrome, hemorrhagic or ischemic stroke, and primary headache disorders, including migraine and cluster headaches.

CNS infections cause altered mental status and meningismus but can usually be distinguished by the presence of fever.

### Diagnostic Testing

A non–contrast-enhanced head CT scan should be obtained emergently when SAH is suspected (Fig. 93.1). For acute hemorrhages less than 24 hours old, the sensitivity of third generation multidetector row CT scanners in identifying hemorrhage is greater than 90%; however, sensitivity decreases to approximately 50% by the end of the first week. There is one well-designed, prospective study that demonstrated in patients scanned within the first 6 hours following the onset of headache, CT was both 100% sensitive and 100% specific for SAH. However, current guidelines still recommend follow up lumbar puncture (LP) when CT is nondiagnostic. Until additional studies are performed, we recommend a LP be performed in CT negative patients suspected of having a SAH.

Interpretation of LP results can be challenging because up to one-third of spinal fluid analyses contain blood or blood degradation products. To differentiate a traumatic LP from SAH, the patient’s CSF should be spun and the supernatant observed for xanthochromia. This yellowish pigmentation is secondary to the metabolism of hemoglobin to pigmented molecules of oxyhemoglobin and bilirubin, a process that can take up to 12 hours to occur. Prospectively gathered data indicate that visual inspection for xanthochromia alone may not diagnose all cases of SAH.

The method of comparing the red blood cell (RBC) count in the first and the last tubes of cerebrospinal fluid (CSF) has not been shown to be accurate, and SAH cannot be ruled out if a substantial numbers of RBCs persist in tube 4. However, a RBC count of less than 100 in tube 4 makes aneurysmal SAH unlikely. CSF xanthochromia in association with normal findings on the CT scan is suggestive of SAH. After the diagnosis is established, angiography should be performed to study the vascular anatomy and to identify the source of hemorrhage.

In lieu of a non-contrast CT followed by LP, the emergency clinician can order a non–contrast-enhanced head CT scan followed by computed tomography angiography (CTA); this is reasonably sensitive and may be appropriate for patients considered to be at lower risk of disease, patients refusing a LP, and patients in whom a LP cannot be performed. Concerns of additional radiation exposure and contrast agent toxicity need to be weighed against the risks of a LP.

A normal non–contrast-enhanced head CT scan followed by a normal spinal fluid analysis definitively rules out SAH and does not need to be followed with angiography, even in patients at high risk of disease. However, this strategy does not rule out other causes of thunderclap headache that may be in the differential diagnosis, such as carotid artery dissection, cerebral venous sinus thrombosis, and reversible cerebral vasoconstrictor syndrome.

Up to 90% of patients with SAH have cardiac arrhythmias or electrocardiographic abnormalities suggestive of acute cardiac ischemia, which may lead to an erroneous primary cardiac diagnosis. Typical electrocardiographic findings include ST-T wave changes, U waves, and QT prolongation.

Decision rules exist to help risk stratify patients with possible SAH; however, high sensitivity is achieved at the expense of specificity. Decision rules can help standardize evaluations but have not significantly reduced current investigation rates (CT scanning and LP).

### Management

The management of SAH is aimed at treating acute medical and neurologic complications, preventing recurrent hemorrhage, and forestalling the ischemic complications of vasospasm. Because of an altered level of consciousness, patients with SAH of grade 3 or higher are at risk for respiratory depression and hypercapnia, which can lead to further increases in intracranial pressure (ICP); therefore, these patients require early endotracheal intubation. Blood pressure should be closely monitored because of the risk of continued bleeding or recurrent hemorrhage. Nimodipine, a calcium channel blocker, should be started soon after a diagnosis of aneurysmal SAH is made to lessen the likelihood of poor outcome due to vasospasm, even if the patient’s blood pressure is normal. Because nimodipine may cause transient hypotension in some patients, hemodynamic monitoring is required during its administration. The recommended dosage is 60 mg by mouth or nasogastric tube every 4 hours. Antifibrinolytics (eg, aminocaproic acid) are used to reduce the risk of early rebleeding in patients with an unavoidable delay in obliteration of the aneurysm in the absence of contraindications. Corticosteroids have not been demonstrated to be of benefit.
Blood pressure management in SAH should be determined by the patient’s clinical status with involvement of the treating neurosurgeon. The typical treatment goal is a systolic blood pressure below 160 mm Hg or a mean arterial pressure below 130 mm Hg unless vasospasm is present.

Analgesics, including opioids, should be used for persistent headache. In patients who are nauseated or at risk for vomiting, antiemetics should be administered. Agitated patients require sedation, and all patients should be placed at bed rest in a quiet and dark environment. Clinically evident seizures should be treated with anticonvulsants, but the prophylactic use of these drugs is controversial. For definitive management, endovascular coil embolization is preferable to neurosurgical clipping, but this decision is based on size, location, and morphologic features of the aneurysm, as well as local expertise.

Disposition
A majority of patients with ruptured aneurysms require hemodynamic and ICP monitoring in an intensive care setting.

Intracranial Neoplasm

Principles

Headache is the most common presenting complaint among patients with brain tumors. It is less common in older patients with brain tumors, presumably because of age-related atrophy. Headache can be caused by primary neoplasms of the CNS, as well as by metastatic lesions. The most common causes of metastasis are lung and breast carcinoma, followed by malignant melanoma and carcinoma of the gastrointestinal tract.

The headache of intracranial neoplasms can be caused by several mechanisms, including traction on pain-sensitive structures (such as, meninges or larger cerebral vessels), or it may be a symptom of increased ICP or hydrocephalus. The pain patterns produced are highly variable, depending on the location and size of the mass and the structures involved. Rapidly growing tumors are more likely to be associated with headache.

Clinical Features

The location of the headache may be ipsilateral, contralateral or bilateral and does not predict tumor location. The typical patient present with complaints of a worsening headache that has been present for weeks to months. The headache may have been present initially only on awakening (most likely in patients with increased ICP), gradually becoming continuous. The classic triad of brain tumor headache—sleep disturbances, severe pain, and nausea and vomiting—is seen in a minority of patients. Vomiting, when it is present, may be projectile and not preceded by nausea and often can be attributed to increased ICP. If increased ICP is present, the headache often is bilateral and worsened by coughing, sneezing, bending, defecation, and sexual intercourse. Other presentations of intracranial neoplasms include seizures, personality changes, and cognitive difficulties.

Differential Diagnoses

A number of disease processes can mimic brain tumor headache. These include other space occupying lesions, such as an abscess or an intra-axial or extra-axial brain hemorrhage; diseases associated with increased ICP, such as idiopathic intracranial hypertension; and a vasculitis, such as giant cell arteritis (GCA). Once malignant causes of headache have been excluded, many of these patients will be diagnosed with a chronic headache disorder, such as chronic migraine, chronic tension-type headache, or new daily persistent headache, which is a primary headache disorder, characterized by abrupt onset and unremitting course.

Diagnostic Testing

The diagnosis of brain tumor headache may be suspected from the history and neurologic examination. Early in the course, patients may present with headache and an intact neurologic examination, although the majority of intracranial neoplasms will eventually cause focal neurologic deficits. Neuroimaging with CT or MRI is the most efficient way to confirm the diagnosis. Contrast enhancement on CT often improves the identification of the underlying mass lesion and helps differentiate it from other causes, including abscess, hematoma, and vascular malformation.

Management

The treatment of headache associated with brain tumor depends on the type of tumor, patient functional status, and stage of the disease. Management consists of urgent referral to specialty care and treatment of any acute complications, including increased ICP and seizures. For patients who present with symptoms suggestive of increased ICP (eg, headache, nausea, vomiting, confusion, weakness), treatment with corticosteroids often provides dramatic temporary relief of headache and other symptoms of increased ICP. Analgesics may also be necessary. Dexamethasone is used most often to treat edema associated with brain tumors. It has several advantages over other glucocorticoids, including a longer half-life, reduced mineralocorticoid effect, and lower associated incidence of cognitive and behavioral complications. The exact dose of steroids necessary for each patient varies in accordance with histologic features, size, and location of the tumor and the amount of edema present. In general, most patients require between 8 mg and 16 mg of dexamethasone per day. An appropriate starting dosage in the ED is 10 mg IV, followed by 4 mg every 6 hours.

Patients who have a seizure should receive a first generation AED, such as phenytoin, carbamazepine, or valproate; a second generation AED (such as, levetiracetam) is an alternative especially if the patient has liver disease. The choice of AED should be made in consultation with the specialist assuming care for the patient. Empirical or prophylactic treatment with AEDs does not appear to delay or to prevent the onset of seizure activity and may expose the patient to unnecessary complications and toxicity.

Disposition

Patients with brain tumor headache should be managed in consultation with the patient’s primary health care team. Hospitalization versus discharge will depend upon the severity of the patient’s presentation.

Giant Cell Arteritis

Principles

GCA is an inflammatory vasculopathy that occurs in medium and large arteries with well-developed wall layers and adventitial vasa vasorum. It typically involves the major branches of the aorta and has a predilection for the extracranial branches of the carotid artery (eg, temporal and occipital arteries). It can involve the ophthalmic, vertebral and distal subclavian arteries, as well as the thoracic aorta. GCA is often named temporal arteritis because it commonly affects the superficial temporal arteries.

The mean age at onset of GCA is 71 years old, and it is rare before 50 years old. Women are affected more commonly than men. Pathologically, the arteritis causes an inflammatory...
infiltrate in the arterial wall resulting in intimal hyperplasia and subsequent stenosis and occlusion, leading to a variety of ischemic complications. In the vast majority of cases, loss of vision is due to arteritic anterior ischemic optic neuropathy (AAION), which is almost always caused by narrowing or occlusion of the posterior ciliary arteries.

Clinical Features

Temporal arteritis is the most typical presentation of GCA and presents with a broad spectrum of clinical features attributable to ischemia on the one hand and systemic inflammation on the other hand (Box 93.4). Headache is the most common initial manifestation and occurs in more than 70% of patients.38 The headache often is of 2 to 3 months’ duration and can be continuous or intermittent; it can worsen at night or on exposure to cold. The pain may be described as sharp, throbbing, boring, or aching and usually is localized to the temporal region but may occur anywhere in the head. The physical examination may reveal tenderness over the scalp in the area of the temporal artery, with exacerbation of the pain by wearing a hat or resting the head on a pillow. Patients also can experience jaw claudication secondary to vascular insufficiency of the masseter and temporalis muscles. Systemic signs and symptoms are often present, including fever, anorexia, and weight loss. Approximately 40% of patients develop symptoms of polymyalgia rheumatica, pain in their large proximal joints, with symptoms referable to the neck, torso, and lower back. The pain and stiffness are typically worse in the morning and lessen as the day goes on.

The most serious complication of GCA is permanent visual loss, which occurs in approximately 15% of patients.39 Amaurosis fugax can occur before permanent visual loss. Other complications include peripheral neuropathies, transient ischemic attacks, and stroke. The physical examination may reveal abnormalities of the temporal arteries best detected by light palpation just anterior to the temporal artery. The majority of patients will have significant elevations of both the erythrocyte sedimentation rate (ESR), usually to more than 50 mm/hr and often more than 100 mm/hr, and C-reactive protein (CRP), as well as the presence of thrombocytosis and anemia. The sensitivity of an elevated ESR or an elevated CRP has been reported in the range of 85%, but their specificity is only 30%.40 However, only 4% of patients with GCA have a normal ESR and CRP at the time of diagnosis. In patients in whom there is high suspicion of disease, a temporal artery biopsy should be performed even if both of these biomarkers are normal.41 Some imaging modalities may eventually aid in the diagnosis of GCA. Color duplex ultrasonography of the temporal arteries may reveal a peri-luminal hypo-echoic halo representing vessel wall edema; however, it is highly operator dependent and its diagnostic value needs to be further determined. High resolution MRI of the temporal arteries has also been studied, but more data is needed before it can be recommended.

Diagnostic Testing

The diagnosis of GCA is based on the history and physical examination, laboratory and imaging studies, and biopsy of the temporal artery. The majority of patients will have significant elevations of both the ESR and CRP at the time of diagnosis. In patients in whom there is high suspicion of disease, a temporal artery biopsy should be performed even if both of these biomarkers are normal. Some imaging modalities may eventually aid in the diagnosis of GCA. Color duplex ultrasonography of the temporal arteries may reveal a peri-luminal hypo-echoic halo representing vessel wall edema; however, it is highly operator dependent and its diagnostic value needs to be further determined. High resolution MRI of the temporal arteries has also been studied, but more data is needed before it can be recommended.

Management

Patients who present with visual symptoms (such as, amaurosis fugax or diplopia) must be treated emergently with glucocorticoids, because they are at risk for visual loss, which is typically permanent. Given available evidence, we believe these patients should be treated with IV pulse therapy (eg, 1000 mg of methylprednisolone per day for 3 consecutive days) to optimize immunosuppression and suppress tissue edema. For patients without visual symptoms, lower doses of steroids, in the range of 40 to 60 mg/day of prednisone should be used.42

Disposition

Patients with GCA should be managed in consultation with appropriate specialists, including neurology, ophthalmology, and rheumatology.

Carotid and Vertebral Artery Dissection

Principles

Approximately 2% of all ischemic strokes are caused by CAD. In patients younger than 50 years old, CAD is the most frequent cause of ischemic stroke and accounts for 10% to 25% of cases. These values likely underestimate the true incidence because patients with minimal symptoms are often not diagnosed. Although dissections may occur spontaneously, a careful history frequently identifies an association with sudden neck movement or trauma preceding the event. Reported mechanisms include neck torsion, chiropractic manipulation, coughing, minor falls,
heavy lifting, various sports including basketball and volleyball, sexual intercourse, childbirth, and motor vehicle collisions. Early symptoms and signs may be subtle, and delays in diagnosis are common in the absence of neurologic findings. The median delay from symptom onset to diagnosis can be several days.

The pathologic lesion in CADs is intramural hemorrhage within the media of the arterial wall. The hematoma can be localized or extend circumferentially along the length of the vessel, resulting in partial or complete occlusion. Damage to the intima results in platelet aggregation and thrombus formation further compromising vessel patency or causing distal embolization. The timing of these events is variable, and a patient may experience symptoms of cerebral ischemia days to years after dissection.

Clinical Features

The typical presentation of CAD is the abrupt onset of pain in the head or neck, often in association with symptoms resulting from ischemic consequences of the dissection and emboli. Neurologic findings secondary to cerebral ischemia usually occur within the first few hours following the onset of the headache or neck pain. Although carotid dissection and vertebral artery dissection have many commonalities, their clinical presentations have some unique features.

**Carotid Artery Dissection.** The classic triad of symptoms for carotid artery dissection includes (1) unilateral headache or neck pain, sometimes radiating to the ipsilateral eye; (2) ipsilateral partial Horner’s syndrome; and (3) either blindness, due to retinal ischemia, or contralateral motor deficits, caused by cerebral ischemia. However, this complete triad is only present in a minority of patients. The headache is often severe and throbbing but may be subacute and similar to previous headaches and may be associated with pulsatile tinnitus.

Acute severe retro-orbital pain in a previously healthy person with no history of cluster headaches is suggestive of carotid dissection. Patients with a carotid dissection are at risk of sustaining embolic cerebral ischemia. Warning symptoms include transient ischemic attacks, amaurosis fugax, episodic lightheadedness, and syncope. Spontaneous dissection of the carotid artery has a favorable prognosis and recurrence is uncommon. Factors associated with a worse prognosis include older age, occlusive disease on angiography, and stroke as the initial presenting symptom.43

**Vertebral Artery Dissection.** Vertebral artery dissections are less common than carotid dissections. The classic presentation is that of a relatively young person with severe, unilateral posterior headache and a rapidly progressive neurologic deficit with symptoms of brainstem and cerebellar ischemia. Common findings include vertigo, severe vomiting, ataxia, diplopia, hemiparesis, unilateral facial weakness, and tinnitus. Stroke severity tends to be lower than that seen with carotid dissection. Spontaneous vertebral artery dissection appears to be relatively rare. Approximately 10% of patients who develop a vertebral dissection die during the acute phase, secondary to massive stroke. For patients who survive, the prognosis is usually good.44

**Differential Diagnoses**

The differential diagnoses of unilateral headache and neck pain with or without Horner’s syndrome include migraine and cluster headache. Cluster headache in particular can present with ptosis. Cervical arterial dissection may present with an abrupt onset of severe headache, which may be confused with SAH or other vascular causes of headache. For patients who present with symptoms of cerebral ischemia, both ischemic and hemorrhagic stroke should be considered as possible etiologies. Conversely, CAD should be considered in patients who present with acute stroke, particularly younger patients.

Diagnostic Testing

Identification of patients with dissection can be challenging especially in the absence of cerebral ischemia. A non–contrast-enhanced head CT scan is often normal in uncomplicated dissection. Digital subtraction angiography remains the diagnostic gold standard, although several studies have found CTA and magnetic resonance angiography (MRA) to be reasonably sensitive and an appropriate choice for initial screening. Figure 93.2 shows an example of carotid artery dissection on MRI. Duplex imaging is not sufficiently sensitive to rule out disease.45

Management

CAD patients with acute ischemic stroke are candidates for thrombolytic therapy. Studies have shown this treatment to be safe with efficacy similar to stroke from other causes.46 For patients with CAD without acute ischemic stroke, the primary goal of treatment is the prevention of cerebral ischemic complications. The role of antiplatelet agents versus anticoagulation with heparin remains unclear. A Cochrane Review published in 2010 found no significant difference in efficacy between these two modalities, although it was based solely on observational studies.46 Recently, the first randomized study was published and found that recurrent stroke at 3 months is rare with no significant difference in outcome between those patients treated with antiplatelet agents or anticoagulation.47

Disposition

Patients with CAD should be admitted to the hospital for monitoring and further management.

**Cerebral Venous Thrombosis**

**Principles**

Thrombosis of the intracranial veins and sinuses is a rare disorder causing approximately 1% of all strokes. It typically presents with headache and disproportionately affects younger individuals without traditional cerebrovascular risk factors.47
There are multiple causes for CVT, and risk factors are classically linked to the Virchow triad of blood stasis, blood vessel wall abnormalities, and a hypercoagulable state. Both genetic and acquired prothrombotic conditions have been associated with CVT. Inherited thrombophilias such as antithrombin III, protein C and protein S deficiencies, and factor V Leiden mutation are the most common genetic causes. Acquired causes for CVT include pregnancy and the puerperium, malignancy, head trauma, surgery, parameningeal infections, and exogenous hormones, such as oral contraceptives. Other causes include inflammatory systemic disorders, including vasculitis, inflammatory bowel disease and connective tissue disorders, and neurosurgical procedures.

Clinical Features

Clinical findings in CVT usually fall into two major categories, depending on the mechanism of neurologic dysfunction: (1) Those that are related to increased ICP due to impaired venous drainage, and (2) those related to focal brain injury from venous resulting in ischemia, infarction, or hemorrhage. Diffuse headache increasing in severity over days to weeks is the most common symptom experienced by patients with CVT and is often associated with increased ICP. Focal neurological findings, when present, are related to the region of the brain that has been injured and bilateral brain involvement may occur. Seizures, both focal and generalized, frequently occur. Ocular findings associated with CVT include orbital pain, proptosis, chemosis, extraocular muscle paralysis, and papilledema.

Differential Diagnoses

The differential diagnoses of early CVT, when symptoms are limited to headache and papilledema, include brain tumor and idiopathic intracranial hypertension. Late presentations of CVT include altered sensorium, seizures, and focal neurological deficits. At this point, the differential diagnoses includes ischemic and hemorrhagic stroke; intracranial infections, such as brain abscess, meningitis, and encephalitis; and systemic conditions, including sarcoidosis and systemic lupus erythematosus. With CVT, neurological findings do not follow a typical arterial territory, and the presence of papilledema is suggestive of CVT. CSF findings and neuroimaging studies help differentiate CVT from these other conditions.

Diagnostic Testing

Routine blood work including a complete blood count (CBC), chemistry panel, ESR, and clotting studies, including a prothrombin time (PT) and partial thromboplastin time (PTT) should be obtained in all patients with suspected CVT. These studies are helpful in determining the presence of an underlying hypercoagulable state, an infectious process, or an inflammatory disorder contributing to the development of CVT. A normal D-dimer is helpful for patients with a low probability of CVT and, along with the clinical findings, can be used to exclude the diagnosis in individual patients at low risk of disease.46,48 The definitive diagnosis of CVT is based on neuroimaging of the area of thrombosis. Noncontrast CT by itself is an insensitive test, but it may reveal nonspecific late lesions, such as an infarct, hemorrhage, or edema. Occasionally, hyperdensity of a cortical vein or sinus may be seen. The key to diagnosis is to image the venous system itself. This is best accomplished by a combination of MRI to visualize the thrombosed vessel and magnetic resonance venography (MRV) to detect nonvisualization of the same vessel.28 CTA and CTV may also be used to visualize the cerebral venous system, especially in patients who have a contraindication to MRI.

Management

Patients with CVT should be anticoagulated to prevent propagation of the thrombosis and development of embolic complications (eg, pulmonary embolism). Treatment is adjusted dose unfractionated heparin or weight-based low–molecular-weight heparin in full anticoagulant doses, regardless of the presence of intracerebral hemorrhage.25 In patients whose clinical condition worsens despite anticoagulation, thrombolysis or thrombectomy may be considered in centers with expertise in interventional procedures. Seizures are treated with antiepileptic drugs.

The prognosis with CVT is based on the underlying etiology, the patient’s condition at time of diagnosis, and the development of complications. The overall mortality is low compared with other types of strokes, but morbidity may be increased with delays in recognition and treatment.46

Disposition

Patients with CVT require hospitalization, preferentially to a stroke unit, for systemic anticoagulation.

Idiopathic Intracranial Hypertension

Principles

Although this disease is sometimes called pseudotumor cerebri or benign intracranial hypertension, the term idiopathic intracranial hypertension (IIH) best reflects current understanding of the pathophysiology and the fact that this disorder is not benign, because permanent visual loss can occur. The term pseudotumor cerebri syndrome includes both IIH and other conditions (eg, systemic lupus erythematosus) that can cause a similar clinical presentation.51 Compared with other headache disorders, IIH is a relatively uncommon neurologic disease seen primarily in young obese women of childbearing age. Several predisposing factors have been suggested, including antibiotics (most commonly tetracyclines), vitamin A and retinoids, and human growth hormone. The pathophysiologic mechanism of this disease is not understood, but it is often attributed to an imbalance between CSF production and reabsorption.

Clinical Features

Clinical and diagnostic criteria for IIH are listed in Box 93.5. The most prominent symptom is generalized headache, which is often gradual in onset and of moderate intensity. No specific localizing pattern has been documented, although in some patients the headache is worsened by eye movement. It may awaken the patient

BOX 93.5

Criteria for Diagnosis of Idiopathic Intracranial Hypertension

| Symptom/Sign                                                                 |
|                                                                             |
| Headache that remits with normalization of CSF pressure                      |
| Papilledema                                                                 |
| Nonfocal neurologic examination                                              |
| May have CN VI palsy                                                        |
| Increased CSF opening pressure                                               |
| >250 mm in adults                                                           |
| >280 mm in children                                                         |
| Normal CSF diagnostic studies                                               |
| Normal neuroimaging studies                                                 |
| No other cause of increased ICP identified                                  |

CN, Cranial nerve; CSF, cerebrospinal fluid; ICP, intracranial pressure.
from sleep and is exacerbated by bending forward and the Valsalva maneuver, both of which impede cerebral venous return. Visual complaints are common, and patients may experience transient visual obscurations (TVOs), which are momentary blackouts of vision most likely due to temporary disruption of the microcirculation to the optic nerve head. They usually occur with postural changes and are not predictive of permanent visual loss. Patients may also complain of nausea, vomiting, dizziness, and pulsatile tinnitus. The physical examination will reveal papilledema and visual field defects or visual loss occurs in up to 50% of patients. Fortunately, in the majority of patients, visual defects are reversible with treatment. On occasion, a sixth nerve palsy (ie, a false lateralizing sign) is noted.

**Differential Diagnoses**

The differential diagnoses of IHH include other causes of increased ICP in a patient presenting with headache. Important considerations include CVT, mass lesions, obstructive hydrocephalus, and leptomeningeal infiltration by neoplastic or infectious processes.

**Diagnostic Testing**

MRI with MRV is the preferred modality for diagnosing IHH because of its ability to not only detect mass lesions and hydrocephalus but also CVT and other meningeal processes. If neuroimaging is normal, a LP should be performed in the lateral decubitus position to measure CSF opening pressure and to obtain CSF diagnostic studies, including cell counts, protein, glucose, cultures, and cytology. An opening pressure of 250 mm H₂O or more (normal 70 to 180 mm H₂O) is necessary to make the diagnosis. An ophthalmology consult should also be ordered for detailed visual field testing.

**Management**

Many patients present without visual field loss, and symptomatic therapy is all that is necessary. Removal of a large amount of CSF (>20 mL) to decrease CSF pressure to relieve the patient’s headache is recommended in all treatment guidelines for IHH. We believe this should be considered for all patients with headache caused by IHH; although the benefit of this practice has not been established in clinical studies. CSF is produced relatively quickly, which limits the duration of benefit. In patients with evidence of visual field loss, treatment with medications to lower ICP is indicated. Acetazolamide is the most potent medication for lowering ICP, and the usual starting dosage is 500 mg twice a day. Other medications that have been used include furosemide, topiramate, and steroids. If a patient is not responsive to medications or has progressive symptoms, referral to an ophthalmologist for optic nerve sheath decompression or a neurosurgeon for a CSF diversion procedure (eg, lumboperitoneal or ventriculoperitoneal shunt) may be indicated.

**Disposition**

Because visual loss can occur early or late in the course of IHH, appropriate specialists including ophthalmology and neurology should be involved in the patient’s evaluation, treatment, and disposition.

**Post-Dural Puncture Headache**

**Principles**

Post-dural puncture headache (PDPH) is a frequent complication of dural puncture, whether performed for diagnostic or therapeutic purposes or accidentally, as a complication of epidural anesthesia. The incidence is highest in the 18- to 30-year age group, and it is uncommon in young children and in adults older than 60 years old. Other than age, risk factors include female gender, low body mass index (BMI), and history of chronic headache.

The pathophysiology of PDPH is not entirely clear. The most likely explanation is a persistent CSF leak that exceeds CSF production, resulting in CSF hypotension. If sufficient CSF is lost, the brain descends in the cranial vault when the patient assumes the upright position, leading to increased traction on the pain fibers. Thus the headache is characteristically positional and increases with the upright position and decreases with recumbency. The amount of time a patient remains recumbent after LP does not appear to affect the incidence of headache.

Certain equipment related factors have been implicated as causes of PDPH, including the size or diameter of the spinal needle, the orientation of the bevel during the procedure, and the amount of fluid withdrawn. Smaller-diameter needles (eg, 20- or 22-gauge cutting needle) cause less leakage, and it is postulated that insertion of the needle with the bevel up (ie, bevel pointing up when the patient is in the lateral position) minimizes damage to the dural fibers. Use of atraumatic needles (eg, Whitaker or Sprotte) also has been shown to reduce the incidence of PDPH. If atraumatic needles are not available, we recommend using a 20- or 22-gauge cutting needle when possible.

**Clinical Features**

The cardinal feature of PDPH is orthostatic or positional headache that is precipitated by the upright position and relieved when the patient lies down. About 90% occur within the first 72 hours after the LP and typically resolve within 1 week. The headache is often described as bilateral and throbbing, frequently in the frontal or occipital regions. Associated signs and symptoms include neck stiffness, nausea, vomiting, auditory disturbances including tinnitus and hypoacusis, and photophobia.

**Differential Diagnoses**

For most patients, PDPH is a benign disorder. However, in patients who do not respond to standard treatment modalities, other secondary headache disorders must be considered. This is especially true in postpartum period where CVT is an important consideration.

**Diagnostic Testing**

The diagnosis of PDPH is based on clinical features, and most patients have a benign course that requires no diagnostic testing. Spontaneous CSF leaks present with orthostatic headaches, which are sometimes severe and should be considered in the absence of a recent LP. The diagnosis is made when low CSF pressures are found on LP. In the postpartum period, CVT can be excluded with MRV.

**Management**

Most PDPHs resolve spontaneously within 5 to 7 days with bed rest, adequate hydration, and mild analgesics. For persistent headaches, methylxanthine agents (such as, caffeine and aminophylline) have been used, but their efficacy has not been proven. We do not recommend their routine use in the ED. For severe headaches that do not respond to conservative measures, an epidural blood patch (EBP) should be used. This procedure involves the injection of 15–30 mL of autologous blood into the epidural space near the site of the original dural puncture resulting in a...
blood clot that seals off the dural hole. EBP has a very high success rate and should be used for PDPH that does not respond to conservative measures.58

Disposition
The vast majority of patients with PDPH will have a benign course requiring only conservative treatment. For patients with persistent complaints, consultation with anesthesia or radiology for an EBP should be considered. If a patient does not respond to an EBP, other secondary causes of PDPH should be considered, especially in postpartum patients.

Post-Traumatic Headache

Principles
Headache is the most common symptom following a concussion or other traumatic brain injury (TBI). It is often part of a complex post-concussive syndrome that can include dizziness, fatigue, insomnia, irritability, memory loss, and difficulty with concentration. Persistent headache occurs in over 50% of patients who have suffered a TBI.59 Paradoxically, patients with milder injuries are more likely to report persistence of symptoms, as are patients with preexisting headache disorders. For the emergency clinician, management of post-traumatic headache (PTHA) is different in the immediate aftermath of trauma, when excluding life-threatening emergencies exist. The pathophysiologic mechanism for the symptoms is unclear and may have both anatomic and functional components.

Clinical Features
By international criteria, PTHA develops within 7 days of the injury or regaining consciousness. Acute PTHA resolves within 3 months, whereas persistent PTHA persists beyond 3 months. Patients in whom PTHA develops after minor head injuries have normal findings on neurologic examination and neuroimaging studies. Most patients are concerned about the cause of the headache more than about the headache itself. PTHA may assume a variety of characteristics, including the pulsating unilateral pain and associated features of migraine, the bland, squeezing pain of tension-type headache, or nonspecific headache often relating to the musculature of the neck.

Differential Diagnoses
In the acute setting, pathological causes of headache including intracranial hemorrhage, or skull or cervical fractures should be excluded. Cervical strain and subtle oculomotor nerve palsies are additional etiologies of PTHA that should be considered. Beyond the acute setting, it may be difficult to distinguish PTHA from migraine or tension-type headache, a distinction that, as time passes, becomes less important.

Diagnostic Testing
In the acute setting following TBI, traumatic injuries to the brain, skull, and neck should be evaluated using available clinical decision rules (see Chapter 34). Patients who return to the ED with persistent symptoms after normal initial imaging should be assured that follow-up imaging is not required, assuming the patient has a normal neurologic examination and is not using anticoagulants or antiplatelet medication.

Management
There is insufficient evidence to determine the optimal treatment of PTHA. We recommend the same armamentarium of medications used to treat acute primary headaches, specifically, antiemetic dopamine antagonists such as metoclopramide or prochlorperazine, and NSAIDs. Opioids should be avoided.

Disposition
Patients with PTHA should be discharged home with outpatient follow-up.

Hypertensive Headache

Principles
The relationship between elevated blood pressure and headache is unclear. Ambulatory blood pressure monitoring studies have not demonstrated an association, although these studies are limited by relatively modest blood pressure elevations during the study period. In the ED, nearly one-quarter of patients who present to an ED with headache have a systolic blood pressure above 150 mm Hg or diastolic blood pressure over 95 mm Hg. Patients who present with headache are more likely to have a markedly elevated blood pressure than patients with other chief complaints. However, the causal pathway, if one exists, is not apparent based on current evidence. In fact, both chronic hypertension and acute elevation in blood pressure have been linked to decreased pain sensitivity in animal and human models. International criteria attribute headache to elevated blood pressure when the pressure is greater than 180 mm Hg systolic or 120 mm Hg diastolic and when the headache resolves with resolution of the elevated blood pressure.60

Clinical Features
The headache of severe hypertension is generally characterized as bilateral and throbbing. Early reports of a typical hypertensive headache come from patients with marked, untreated hypertension, who had early morning headaches that were of greatest intensity before the patient arose and typically resolved as the patient engaged in morning activities.

Differential Diagnoses
Based on population prevalence, the most likely diagnoses in patients with elevated blood pressure and headache are migraine or tension-type headache with concomitant hypertension.60 Pre-eclampsia, a disorder characterized by elevated blood pressure and headache, should be considered in patients in the latter stages of pregnancy and the recent postpartum period. Posterior reversible encephalopathy syndrome is characterized by white matter changes on diagnostic imaging. Malignant hypertension, including drug-induced hypertension, requires evidence of end organ damage.

Diagnostic Testing
Absent focal neurological deficits, abnormal findings on retinal examination, or visual deficits, a diagnostic evaluation is not indicated.

Management
It is uncertain if strategies aimed at lowering the blood pressure acutely will alleviate the headache. We recommend use of
antidopaminergic or nonsteroidal agents, with use of antihypertensive agents reserved for patients with evidence of end organ damage. Oral antihypertensive therapy may be prescribed in the ED if timely outpatient follow-up cannot be assured.

**Disposition**
In the absence of objective neurological symptoms, patients with hypertensive headache do not require admission to the hospital. Elevated blood pressure should be treated on an outpatient basis.

**KEY CONCEPTS**

- The goals of headache evaluation in the ED are (1) to distinguish between benign primary headache disorders and potentially life-threatening secondary causes of headache and (2) to treat the headache pain effectively and rapidly without causing undue side-effects.
- Patients with the following headache presentations are at risk for serious underlying disease: sudden explosive headache; first or “worst-ever” headache; new-onset headache after the age of 50 years; headache associated with papilledema, alteration in or loss of consciousness, or focal neurologic symptoms; subacute headache with increasing frequency or severity; headache associated with fever, cancer, or immunosuppression; and headache triggered by exertion, sexual activity, or Valsalva maneuver.
- The need for diagnostic studies is dictated by the suspected secondary cause of headache.
- Sumatriptan medications are the first line therapy for migraine headaches.
- Patients with migraine treated in the ED need to be discharged with a “rescue plan” if the headache reoccurs.
- High-flow oxygen will terminate the majority of cluster headaches.
- Opioids are not first line treatment for primary headaches and are reserved for cases refractory to other interventions.
- The differential diagnosis of sudden severe headache includes SAH, CVT, CAD, and IIH.
- CVT should be suspected in women who have a new type of headache and are pregnant or on birth control pills.
- Carotid artery dissection may result in headache, ptosis, and miosis.
- Patients suspected of having a PTHA should be evaluated for a CN IV or VI neurapraxia and for cervical strain as a cause of their headache.

**Management**
There are no evidence-based treatment options available for RCVS. Goals of treatment include prevention of ischemic and hemorrhagic stroke and elimination of headache. To date, the natural history of this disorder is incompletely understood. Treatment with calcium channel blockers has been described, although when to initiate treatment is unclear.

**Disposition**
Patients with thunderclap headache who have received an appropriate diagnostic evaluation in the ED may be discharged home with appropriate follow-up.

REFERENCES

93.1. Which of the following mechanisms is least likely to play a role in the pathophysiology of migraine headaches?
A. Cortical spreading depression  
B. Pathologic cerebrovascular dilation activates surrounding afferent nerve endings, causing typical pulsating pain  
C. Sensitization of higher-order nociceptive centers in the brainstem and thalamus  
D. Sterile neuropeptide induced inflammatory process  
E. Trigeminal nerve activation  

Answer: B. Trigeminovascular activation, possibly triggered by cortical spreading depression or a sterile neurogenic inflammation, causes activation and sensitization of higher-order nociceptive centers in the brainstem and thalamus. A primary vascular etiology of migraine pain is not supported by available evidence.

93.2. A 42-year-old male presents with the acute onset of a left-sided headache. He had one similar headache approximately 1 year ago that lasted 3 hours, subsided rapidly, and like this one, was associated with alcohol intake. Physical examination is remarkable for an obviously uncomfortable healthy male pacing and rubbing his left temple. You note left conjunctival injection with tearing. What should be the next step?  
A. Computed tomography (CT) scan  
B. Dexamethasone 10 mg intravenously  
C. High-flow oxygen by face mask  
D. Measurement of intraocular pressure  
E. Morphine 10 mg intravenously  

Answer: C. Cluster headaches occur predominantly in men, occur suddenly, and often abate quickly. These headaches are typically unilateral and characterized by a sharp stabbing ocular pain that may be accompanied by a “conjunctivitis” picture, a partial Horner’s syndrome, or unilateral nasal congestion. Alcohol may precipitate. Standard antimigraine agents may be helpful (eg, sumatriptan, antiemetics), but high-flow oxygen is highly effective and very well tolerated. Calcium channel blockers and corticosteroids are useful for preventing subsequent attacks of cluster headache. As with migraines, opioids should be reserved for refractory pain.

93.3. A 29-year-old female presents within 1 hour of the sudden onset of a severe, diffuse headache accompanied by meningismus and vomiting. Emergent computed tomography (CT) scan is negative. Lumbar puncture (LP) reveals 50,000 red blood cells (RBCs) in tube 1 and 30,000 RBCs in tube 4. Opening pressures are normal, and the sample is negative for xanthochromia. What would be the most appropriate next step?  
A. Admission and observation  
B. Cerebrovascular imaging study  
C. Hydration, analgesics  
D. Magnetic resonance imaging (MRI) scan with gadolinium  
E. Subcutaneous sumatriptan 6 mg  

Answer: B. CT scan provides a sensitivity of approximately 90% for the detection of subarachnoid hemorrhage (SAH). A traumatic LP, even with diminishing RBC counts with sequential tubes, cannot differentiate between a SAH and traumatic tap. The lack of xanthochromia is predictable, given the acute onset of headache and the 12 hours required for cerebrospinal fluid (CSF) xanthochromia to develop. A cerebrovascular imaging study, such as computed tomography angiography (CTA), magnetic resonance angiography (MRA), or standard angiography would be required next to exclude a source of bleeding, such as an aneurysm or arteriovenous malformation (AVM).

93.4. A 69-year-old male presents with several months of intermittent left-sided headaches that have been worse at night and occasionally on exposure to cold air. On several occasions, he has noted increased pain while eating. He has had no other symptoms other than modest fatigue. Physical examination is unremarkable with normal vital signs and ophthalmologic and neurologic survey. Laboratory evaluation shows only a mild anemia, with a hemoglobin of 11 mg/dL and normocytic indices. What would be the most appropriate next step?  
A. Computed tomography (CT) scan of the brain  
B. Electrocardiogram  
C. Erythrocyte sedimentation rate (ESR)  
D. Neurology consultation  
E. Ophthalmology consultation  

Answer: C. Temporal arteritis may present with intermittent or continuous symptoms, sometimes associated with fatigue, myalgias, jaw claudication, and mild anemia. The ESR is usually, but not always, diagnostic and would confirm the diagnosis if elevated. Steroids and ophthalmology consultation would then follow. The presence of temporal artery tenderness may be variable because the vasculitis may affect any artery. The diagnosis must be suspected in any elderly patient with recurrent or continuous headaches.

93.5. With cavernous sinus thrombosis, the clinical picture is usually dominated by which of the following?  
A. Facial pain  
B. Lethargy  
C. Nausea and vomiting  
D. Ocular findings such as pain and proptosis  
E. Seizures  

Answer: D. The symptoms may also include paralysis of extraocular movements. Ocular symptoms are most common with thrombosis of the cavernous sinus, rather than one of the other sinuses.
Delirium and Dementia

Gallane Abraham | Leslie S. Zun

OVERVIEW

Cognition is a composite of attention, orientation, memory, language, visual-spatial ability, and executive function. Both delirium and dementia affect cognition but in very different ways and over very different time courses; that said, delirium can occur concomitantly in a patient with dementia making the diagnosis challenging. In the past, terms such as acute confusional state, sundowning, and organic brain syndrome have been used to describe a number of abnormal cognitive states. Organic brain syndrome is a nebulous term that the Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) eschews because the “organic” connotation implies that so-called functional mental disorders are without a biologic basis. The preferred terms are medical or psychiatric etiology. Although the DSM-5 still uses the terms delirium, dementia, amnesic, and other cognitive disorders, the preferred terminology is neurocognitive disorders.

Delirium is characterized by a fluctuating neurobehavioral disturbance typically progressing over a short period. It is a direct consequence of an acute systemic or central nervous system (CNS) stressor. Dementia, on the other hand, tends to follow a more gradual course, with evolution occurring over months to years. Although patients with dementia exhibit confusion, unlike delirium, manifestations of autonomic nervous system abnormalities are minimal or absent and a disturbance in level of consciousness usually is not a feature.

The evaluation of patients who present to the emergency department (ED) with a neurobehavioral disturbance is best conducted in accordance with the following basic guidelines:

1. The first step is to determine whether this state represents delirium or dementia by obtaining a careful history from the patient, family members, and caregivers, employing screening tools for delirium and cognitive assessments for dementia. The clinical findings may be subtle and establishment of the diagnosis can be challenging, especially because delirium may be superimposed on dementia, and dementia remains an independent risk factor for delirium.
2. The second step is to rapidly treat the underlying disorder in patients with delirium.
3. The third step is to establish a supportive environment and employ pharmacological adjuncts as needed.

DELIRIUM

Principles

Background

Delirium is an acute or subacute state of cognitive dysfunction caused by an underlying physiologic condition. Several key features are necessary for a diagnosis of delirium (Box 94.1). Patients with delirium may have disturbances in consciousness, memory, cognition, and perception. These disturbances tend to develop during a short time (hours to days) and are characterized as acute delirium if the symptoms last hours to days or persistent delirium if the symptoms last weeks to months. The disturbance in consciousness may be manifested initially as an inability to focus attention. The fluctuating course of symptoms and inattention are the hallmarks of delirium. Deficiencies in cognition may be manifested by disorientation and memory deficits. Perceptual disturbances include hallucinations and delusions. The delirious patient may be somnolent or agitated, and the thought process may range from mildly disturbed to grossly disorganized. The clinical presentation may be subdued or explosive. The patient’s sleep-wake cycle may be altered or reversed; agitation often is present during the night. There are three types of delirium: hyperactive, hypoactive, and mixed level of activity. Hyperactive type demonstrates hyperactivity with emotional lability, agitation, and may include refusal of care; the hypoactive type demonstrates sluggishness and lethargy; the mixed type is found in a person with a normal level of activity but with disturbance of attention and awareness or fluctuations in activity levels.

Delirium has been reported to be present in up to 24% of the older adults treated in the ED.2 It is a frequently missed diagnosis when standardized screening tools are not used. This is problematic because the mortality rate rises from 10% of those diagnosed in the ED to 56% when it is missed. This increased mortality is associated with a high rate of incontinence, decubiti, and malnutrition.

Predisposing factors for delirium include comorbid illness, dementia, older age, male gender, medications, neurologic deficits, and psychiatric illness (Table 94.1). Precipitating factors include infections, endocrine and metabolic disorders, medications, CNS events, cardiovascular disorders, and iatrogenic related events.

Drug intoxication or withdrawal (including ethanol) are the most common cause of delirium in the younger adult population. Within the older population, drugs are also a common cause of delirium; drugs with anticholinergic properties are often implicated but almost every drug class can be a precipitant. Industrial exposures (eg, carbon disulfide, heavy metals, insecticides, cyanide, carbon monoxide), herbal medications, and ingestion of certain plants (eg, nutmeg, foxglove, jimsonweed, psilocybin-containing mushrooms) are yet other causes of delirium to consider.

Delirium can be a prominent feature of any CNS or systemic infection, particularly in the very young, elders, and immunocompromised patients. All metabolic disorders put patients at risk for delirium with hypoglycemia and hypoxia being the most common. Delirium is also associated with strokes, particularly strokes in the distribution of the nondominant middle cerebral artery and the posterior cerebral artery. CNS vasculitis and paraneoplastic syndromes are additional considerations.

Pathophysiology

At a cellular level, delirium is the result of a widespread alteration in cerebral metabolic activity, with secondary deregulation of neurotransmitter synthesis and metabolism. Both the cerebral cortex and the subcortical structures are affected, producing changes in arousal, alertness, attention, information processing, and the normal sleep-wake cycle.
Diagnostic Criteria for Delirium

FOUR KEY CHARACTERISTICS
• Disturbance in attention and awareness.
• The disturbance develops over a short time period, represents a change from baseline attention and awareness, and tends to fluctuate in severity during the day.
• There are additional disturbances in cognition, such as memory, disorientation language, visual spatial ability, or perception.
• The disturbances are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in context of a coma.

Although the exact pathophysiologic process is not well understood, multiple neurotransmitters have been implicated in causing delirium. Delirium is often associated with a derangement of central cholinergic transmission. Serum anticholinergic activity is increased, and low levels of acetylcholine are seen in elders with delirium. This is most pronounced in patients experiencing delirium secondary to anticholinergic drugs. Increased serotonin levels have been found in hepatic encephalopathy, serotonin syndrome, sepsis, and psychodelic drug ingestion. Some of the disturbances that occur in delirium are deficiencies of substrates for oxidative metabolism (eg, glucose, oxygen); disturbances of ionic passage through excitable membranes; increase in cytokines; imbalance of normal noradrenergic, serotonergic, dopaminergic, and cholinergic homeostasis; and, in some cases, synthesis of false neurotransmitters.

Drugs and exogenous toxins can produce delirium through direct effects on the CNS. Although the limbic system appears to be particularly vulnerable to the effects of drugs, the cerebral hemispheres and the brainstem also can be profoundly affected. Tricyclic antidepressants can cause delirium by cholinergic inhibition; sedative-hypnotics depress activity in the CNS, especially in the limbic system, thalamus, and hypothalamus. Narcotics affect CNS activity primarily by interacting with various opioid receptor sites. Psychodelic drugs probably act as agonists at serotonin receptor sites. Phencyclidine (PCP) inhibits reuptake of dopamine, norepinephrine, serotonin, and α-aminobutyric acid and also may act as a false neurotransmitter.

Hyperthermia and hypothermia can cause delirium due to changes in the cerebral metabolic rate. In hypothermia, cerebral metabolism decreases 6% to 7% for each 1°C decrease in temperature from 35° to 25°C. In hyperthermia, cellular damage with uncoupling of oxidative phosphorylation begins to occur at temperatures higher than 42°C. Patients suffering from heatstroke may have cerebral edema, degenerative neuronal changes (especially involving Purkinje cells of the cerebellum), and petechiae in the walls of the third and fourth ventricles. Delirium occurring at temperatures below 40°C is multifactorial in origin and not caused solely by increased core temperature.

Delirium caused by metabolic abnormalities, such as hypotension, hypernatremia, hyperosmolarity, hypercapnia, and hyperglycemic disorders, is associated with a variety of metabolic disturbances at the neuronal and astrocyte levels. Such disturbances may include impairments in energy supplies, changes in resting membrane potentials, changes in cellular morphology, and changes in the brain water volume.

Most patients with delirium have reduced cerebral metabolic activity. This reduction in cerebral metabolism is reflected by a decrease in the frequency of background electrical activity on the electroencephalogram (EEG). Exceptions are hyperthermia, sedative-hypnotic withdrawal, delirium tremens, and certain drug-induced states, in which the cerebral metabolism is either normal or increased.

Clinical Features

Delirium is often the first manifestation of underlying disease. The natural history of a patient’s delirium can progress from apathy to marked agitation in the course of hours (see Box 94.1). Nonspecific prodromal symptoms such as anxiety, restlessness, and insomnia typically emerge during hours to days.

Key aspects of cognitive impairment should become evident during a careful history and physical examination. Disturbance in attention is central to the diagnosis of delirium. The patient is easily distractible and has difficulty remaining focused on a particular topic or interacting with a single person. Disorientation often accompanies the inattention but is not an invariable feature. The patient usually is disoriented with respect to time and
occasionally to place; in extreme cases, disorientation to person also may be noted. Delirium, however, may be present in a patient who is completely oriented to person, place, and time. A mental status examination that consists solely of questions that assess orientation will not detect delirium in these instances.

The patient with delirium always has some degree of memory impairment, with the greatest impact on short-term memory. Thought processes and speech may be disorganized. Disturbance in the sleep-wake cycle often occurs early in the course of delirium. Perceptual disturbances, including misperception of the environment, poorly formed delusions, and hallucinations, are common. The delirious patient may experience visual, auditory, tactile, gustatory, or olfactory hallucinations. In addition, the delirious patient has a reduced capacity to modulate fine emotional expression and may demonstrate extreme emotional lability.

The cognitively impaired patient may provide an unreliable history. Valuable information often can be obtained from family, friends, and out-of-hospital personnel. Specific inquiry should be made about the patient’s current medical problems and previous medical history, including diabetes, hypertension, kidney or liver disease, immune status, and any neurologic or psychiatric problems. A detailed medication history, including the use of prescribed and over-the-counter medications, dietary supplements, and alcohol or other substances, is essential. Out-of-hospital personnel should be able to provide information about the home environment, medication bottles belonging to the patient or found near the patient, and the possibility of trauma.

The physical examination should begin with a careful assessment of vital signs including pulse oximetry and a pain assessment. The delirious patient often exhibits autonomic nervous system abnormalities on evaluation, including elevated or decreased pulse, blood pressure, respiratory rate, and temperature. The examination also includes assessment of the head for signs of trauma and the pupils for symmetry and light reflex; funduscopic examination for hemorrhage or papilledema; examination of the ears for hemotympanum; evaluation of the neck for nuchal rigidity, bruits, and thyroid enlargement; assessment of the heart and lungs; evaluation of the abdomen for organomegaly and ascites; and examination of the extremities for cyanosis. The skin should be carefully examined for rashes, petechiae, ecchymosis, splinter hemorrhages, and needle tracks.

The neurologic examination includes assessment of the cranial nerves, motor strength, sensation, reflexes, and presence of abnormal movements (eg, ophthalmoplegia, tremor, asterixis, myoclonus). A specific constellation of neurologic findings may suggest a specific diagnosis. One such example is the classic triad of Wernicke’s encephalopathy: ophthalmoplegia, ataxia, and confusion. The reflexes are assessed for symmetry and presence of hyperreflexia or hyporeflexia. Findings that typically suggest either a metabolic or a structural neurologic problem are not necessarily specific for that category of disorder. For example, asterixis is a hallmark of metabolic encephalopathy but can be seen in focal brain disease. Likewise, focal neurologic signs that typically are associated with structural CNS lesions also can be present in various metabolic abnormalities, such as hypoglycemia, hyperglycemia, hepatic encephalopathy, uremia, and hypercalcemia.

The physical examination is not often helpful in determining the specific drug or class of drugs causing acute cognitive impairment. The one exception to this rule is the presence of a “toxidrome,” which is a constellation of signs and symptoms characteristic of intoxication with certain drugs or classes of drugs (see Chapter 139).

Although there are a number of delirium scales found in the literature, the Confusion Assessment Method (CAM) is a validated tool that has a sensitivity of 93% to 100% and specificity of 90% to 95%. Performing the CAM takes 5 minutes, and it is often used in conjunction with other tests (eg, the Mini-Mental State Examination [MMSE] or Richmond Agitation-Sedation Scale [RASS]) to provide a composite baseline of cognition in patients exhibiting symptoms of delirium and dementia (Table 94.2). The CAM has four key features used in screening for delirium: (1) acute onset and fluctuating course, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness. For a definitive diagnosis of delirium, the first two features and one of the last two must be present. It has proved to be a valuable tool because of its ease of administration and high interobserver reliability. In addition, it has been shown to be more sensitive than clinical impression alone.

### Differential Diagnosis

Considerations in the differential diagnosis for delirium include dementia and psychiatric disorders. Dementia, depression, mania, paranoia, and schizophrenia all may resemble delirium but can be distinguished using historical and clinical features such as onset, time course, fluctuating mental status, and inattention (Table 94.3). Unlike delirium, dementia and psychiatric disorders tend to be insidious processes that develop during months to years. Typically, the patient’s vital signs are normal. In addition, cognitive impairment of dementia exhibits little fluctuation during hours or days and occurs primarily in elders. A point worthy of emphasis is that patients with dementia are more likely to develop delirium.

### Diagnostic Studies

Because delirium is generally the manifestation of an underlying disorder, a comprehensive evaluation looking for structural, metabolic, and infectious etiologies is indicated (Table 94.4). Despite these diagnostic evaluations, no cause is found for delirium in up to 16% of patients. An elevated anion gap (>15 mEq/L) may indicate the presence of unmeasured anions, such as ketoacids in diabetic or alcoholic ketoacidosis; lactate in postictal states or

Although it is rarely practical in the ED setting, the EEG can be a valuable diagnostic tool in assessing for nonconvulsive status epilepticus and determining the presence of delirium. Bilateral diffuse symmetrical electroencephalographic abnormalities are a relatively consistent feature of delirium. In most cases, the changes consist of a nonspecific generalized slowing from the baseline activity and can be useful in distinguishing delirium from other neurobehavioral abnormalities.

Management

Delirium is a medical emergency. The outcome depends on the cause, the patient’s overall health status, and the timeliness of treatment. The presence of hyperactive or hypoactive delirium has some prognostic significance. The hypoactive form of delirium tends to be more common in elders and carries a worse overall prognosis, perhaps because it often goes unrecognized. Acute recognition and management of delirium in elders is essential because delirium in this population is associated with increased risk of long-term institutionalization, development of dementia, and increased overall mortality.8

Patients who present with acute delirium should be screened quickly for readily reversible causes, such as hypoglycemia, hypoxia, and narcotic overdose. Acute intoxication requires prompt attention and antidotes provided when available.

Other conditions requiring immediate medical intervention include infections. Patients with signs of acute meningitis or sepsis should rapidly receive antibiotics along with fluid resuscitation. Antibiotics for meningitis should be dosed according to age and predisposing factors (see Chapter 99). Other emergent conditions that may be manifested with delirium and necessitate immediate intervention include severe hypothermia, hyperthermia, and CNS vascular conditions, including hypertensive encephalopathy, acute epidural or subdural hematoma, subarachnoid hemorrhage, and stroke. Patients with Wernicke’s encephalopathy require immediate treatment with 100 mg of intravenous (IV) thiamine, with titration of additional doses until the ophthalmoplegia resolves. Resistance to thiamine may result from hypomagnesemia because magnesium is a cofactor for thiamine transketolase. Glucose administration in patients with severe thiamine deficiency may precipitate Wernicke’s encephalopathy. The specific treatment of delirium tremens (and other alcohol withdrawal syndromes) involves the substitution of a long-acting drug that is cross-tolerant with the alcohol. Benzodiazepines are the agents of choice to reduce agitation and other hyperactive symptoms in delirium tremens (see Chapter 142).

Delirium secondary to dehydration, hyponatremia, hypernatremia, hypercalcemia, and hepatic or renal disease gradually resolves during hours to days with fluid and electrolyte replacement.

Supportive care for all patients with delirium ideally includes an environment with adequate lighting and minimization of sensory overload; the patient should be placed in an area that can be easily observed by staff, and use of stretcher side rails to prevent falls. Use of “sitters” may be necessary to provide continuous supervision. The patient must be protected from self-harm or from injuring other patients or staff. In cases of hyperactive delirium, the patient may need to be initially restrained physically until pharmacologic control takes effect. Physical restraints should be viewed only as a temporizing action, because they can increase agitation and the risk of injury to the patient. They have been associated with injuries and even death by asphyxiation and are not a substitute for pharmacologic control.

Pharmacologic interventions are a cornerstone of behavioral management while the underlying medical condition that caused the delirium is being addressed. The ideal sedating drug should have the following characteristics: low toxicity with minimal anticholinergic effects, ease of administration, short half-life, minimal effects on the cardiovascular and respiratory systems, and no effect on the seizure threshold. Antipsychotics and benzodiazepines have been used in the management of acute agitation in the undifferentiated patient with delirium. The opioids have no role in the management of delirium.

Antipsychotic medications used to treat delirium include the typical antipsychotics, especially the butyrophenones, and the newer atypical antipsychotic agents. Although no one drug is ideal, the typical antipsychotic, haloperidol, continues to be recommended as monotherapy for controlling agitation in acute delirium on the basis of extensive clinical experience.7 The use of the atypical antipsychotic agents for delirium and acute agitation is not well characterized. The newer atypical antipsychotic agents (risperidone, olanzapine, ziprasidone, aripiprazole) may have equal or better efficacy and fewer side effects (especially akathisia and dystonia) for management of acute agitation in the psychiatric population.

As the primary drug for control of hyperactive delirium, haloperidol is a potent dopamine-blocking medication with less anticholinergic and minimal hypotensive effects. The main effect of the drug is anxiolytics and tranquilization. The incidence of extrapyramidal side effects in patients receiving IV haloperidol for management of delirium with agitation is relatively low. Studies of the acute administration of haloperidol report an 8% to 30% incidence of extrapyramidal side effects with akathisias being most common and acute dystonia occurring in less than 10% of patients.

Haloperidol can prolong the QTc interval, more so when given intravenously, but this effect is clinically insignificant in most patients and does not require a pretreatment electrocardiogram. Caution is warranted with use of this agent in patients taking medications that prolong the QTc (eg, class IA and class III antiarrhythmics, certain antibiotics, inhibitors of the cytochrome P450 system) and in patients with acute coronary ischemia, uncompensated congestive heart failure, or hepatic dysfunction. The QTc effect is not usually concerning when the haloperidol is given intramuscularly.

Haloperidol dosing should vary with the patient’s level of agitation, age, weight, and response to treatment. In most patients, 2.5 to 10 mg intramuscularly (adjusted according to weight and comorbidities) is well tolerated as an initial dose, and levels can be titrated as needed. For elders, a lower initial dose of 0.5 to 1.0 mg is recommended. Higher doses may be required for younger patients.

The atypical antipsychotics can be used acutely for management of agitation. These drugs have been studied for use in the psychotic patients and patients with Parkinson’s disease presenting with acute agitation. The mechanism of action includes antagonism of α1-adrenergic, serotonin, muscarinic, dopamine, and histamine receptors. These drugs block the reuptake of dopamine and serotonin, and the newer drugs also have dopamine agonist effects (aripiprazole). Compared with haloperidol, several of these atypical agents (ziprasidone, risperidone, clozapine, and olanzapine) have been shown in nonrandomized case series to control agitation as effectively with less sedation and fewer extrapyramidal side effects. Because of the limited dopamine antagonism effect, atypical antipsychotics are the preferred agent for patients with Parkinsonism and agitation.

Benzodiazepines are also considered effective as monotherapy or used in combination with the typical antipsychotics for the management of acute undifferentiated agitation, intoxication, or withdrawal syndromes.10,11 Lorazepam, a shorter-acting benzodiazepine that undergoes glucuronide conjugation with rapid renal clearance, is the preferred agent for treatment of withdrawal symptoms. Diazepam should be avoided as an agent for treatment of agitated behavior in most delirious patients because of its long
The management of delirium has been identified by The National Institutes of Health Task Force on Research in Emergency Medicine as a specific area requiring further research. Based upon the best available evidence, we recommend screening and treatment of readily reversible causes of delirium and initial non-pharmacological management followed by a selection of pharmacological agents based upon the etiology of delirium and patient comorbidities. We recommend either a benzodiazepine or antipsychotic (typical or atypical) used as monotherapy. As an alternative, a combination of a low-dose antipsychotic plus benzodiazepine (eg, haloperidol 5 mg IM plus lorazepam 2 mg) can be used. The combination approach has been found to be superior to either class alone in the treatment of undifferentiated acute agitation and has the added benefit of minimizing adverse effects.

Disposition

Patients with delirium secondary to acute drug intoxication may be discharged from the ED provided the process readily reverses itself during a short period of observation and the drug has no potentially serious delayed toxicity. For most patients delirious from metabolic, infectious, or CNS processes, hospitalization is necessary for further diagnostic evaluation and treatment. The only readily reversible metabolic problem associated with delirium that can be completely managed in the ED is hypoglycemia.

For most patients without underlying medical illness who have delirium, the outcome is full recovery. After an episode of acute delirium, younger patients may experience mild cognitive dysfunction that lasts weeks to months. Elders, on the other hand, often experience persistent decline in their baseline level of functioning, with loss of at least one activity of daily living after acute delirium. Delirium in older adults hospitalized without baseline dementia is associated with higher 1-year mortality rates, higher rates of institutionalization, and a greater risk for development of dementia. For older adults, an episode of delirium, especially for those with baseline cognitive impairment, can have long-term consequences despite good supportive multidisciplinary care.

DEMENTIA

Principles

Background

Dementia is not a single disease entity but rather a highly variable clinical syndrome characterized by a gradually progressive deterioration of cognitive function. Prognosis depends on the underlying cause (Box 94.2). Dementia is classified as either irreversible (primary degenerative) or potentially reversible (secondary); it is further classified according to the degree of cognitive impairment. Mild dementia implies some impairment of work and social activities; however, the capacity for independent living remains intact. With moderate dementia, independent living is hazardous, and some degree of supervision is necessary. With severe dementia, continual supervision and often custodial care are needed.

Primary degenerative dementias include Alzheimer’s disease, dementia with Lewy bodies, subcortical dementias involving the basal ganglia and thalamus (eg, progressive supranuclear palsy, Huntington’s chorea, Parkinson’s disease), and dementia of the frontal lobe type, which includes Pick’s disease. Dementia with Lewy bodies, clinically manifested by persistent, well-formed visual hallucinations and prominent extrapyramidal movements, has been found to be the third most common type of dementia. With advanced aging, dementia may have mixed causes, with Alzheimer’s disease and vascular dementia frequently coexisting.

A smaller percentage of dementias are attributable to causes, such as anoxic encephalopathy, hepatolenticular degeneration, tumors, and slow virus infections.

Potentially reversible dementias are caused by adverse drug reactions, endocrinopathies, metabolic abnormalities, intracranial processes, and depression. The clinical manifestation is either an acute delirium or an acute or gradual progressive cognitive impairment that reverses once the underlying etiology is addressed and resolved. Drug-induced dementia occurs primarily in elders and can be caused by various psychotropic drugs, antihypertensive medications, anticonvulsants, anticholinergics, and miscellaneous medications, such as L-dopa. Dementia also may be caused by heavy metals and other exogenous agents, such as carbon monoxide, carbon disulfide, and trichloroethylene.

Endocrinopathies and metabolic abnormalities that can cause secondary and potentially reversible dementia include hypothyroidism, hyperthyroidism, parathyroid disease, Addison’s disease,
Intracranial processes, space-occupying lesions, and hydrocephalus may also cause dementia. Repetitive intracranial trauma resulting from contact sports can produce a chronic organic brain syndrome without evidence of hematoma or significant contusion (dementia pugilistica). Intracranial processes that may eventually lead to a chronic organic brain syndrome include infections with low viruses, human immunodeficiency virus type 1 (HIV-1) infection, chronic meningitis (tubercular or fungal), brain abscess, and neurosyphilis. In addition to primary HIV-1 CNS infection, toxoplasmosis, cryptococcal meningitis, malignant disease, and infections due to herpesvirus, cytomegalovirus, varicella-zoster virus, and papovavirus (progressive multifocal leukencephalopathy) can cause progressive cognitive impairment in this compromised group of patients and must be excluded.

There are two categories of primary degenerative dementias that are collectively referred to as dementia and that have the same neuropathologic changes: (1) a presenile dementia seen in younger patients, and (2) senile dementia. Alzheimer’s disease accounts for 60% to 80% of all dementias; vascular dementia (with or without Alzheimer’s disease) accounts for 20%, and the remaining 20% of cases are attributable to more than 50 known causes.

Worldwide, approximately 24.3 million persons suffer from dementia, and 4.6 million new cases are diagnosed yearly. The prevalence is approximately 1% at 60 years old but doubles every 5 years until it reaches 30% to 50% by 85 years old. In 2014, the estimated prevalence of Alzheimer’s dementia was 5 million for adults in the United States aged 65 years or older and is projected 5 years until it reaches 30% to 50% by 85 years old. In 2014, the prevalence is approximately 1% at 60 years old but doubles every 5 years until it reaches 30% to 50% by 85 years old. In 2014, the prevalence is approximately 1% at 60 years old but doubles every 5 years until it reaches 30% to 50% by 85 years old.

The deficits do not occur exclusively during the course of a delirium. Cognitive decline from a previous level of performance in one or more cognitive domains: complex attention, executive function, learning and memory, language, perceptual-motor function, or social cognition. Several clinical features deserve emphasis. Impairment in memory must involve both short-term and long-term memory. The cognitive impairment commonly involves abstract thinking, judgment, and other higher cortical functions. The cognitive impairment must interfere with interpersonal relationships, work, and social activities. Although mild decline in intellectual functioning characterized as inability to learn and retain new information without impairment of daily functions can be part of the normal aging process, gross intellectual impairment of short- and long-term memory or confusion is not normal. Mild cognitive impairment is distinct from early dementia.

The goals of ED evaluation for suspected dementia are (1) to recognize the signs and symptoms of undiagnosed and potentially reversible forms of dementia, (2) to identify the manifestations of acute illness in the demented patient promptly, and (3) to assess the clinical findings in lieu of the patient’s cognitive impairment and facilitate a safe disposition and expedited follow-up.

**Pathophysiology**

Alzheimer’s disease is the best-understood dementia and involves several characteristic anatomic, pathologic, and neurochemical changes. The predominant change is cortical atrophy most prominent in the temporal and hippocampal regions caused by progressive synaptic and neuronal loss in the cerebral gray matter. This atrophy generally is followed by loss of white matter (subcortical atrophy). There is no ischemic component to Alzheimer’s disease. Cell loss does occur with the normal aging process but not to the extent seen in dementia. Not all patients with dementia have gross cerebral atrophy.

Histologic features characteristic of Alzheimer’s disease include extracellular deposition of β-amyloid protein and intracellular neurofibrillary tangles contributing to neuron loss. The abnormal processing of β-amyloid protein is likely central to the pathogenesis of Alzheimer’s disease. The neurofibrillary tangles are intraneuronal paired helical filaments composed of the abnormally phosphorylated protein tau, the structural protein involved in the regeneration of neurites. Senile plaques are extracellular lesions composed of the degenerating neuronal processes and abnormal β-amyloid protein. These plaques are extensively spread throughout the cerebral cortex and do not correlate with the severity of dementia. Other consistent neurohistopathologic changes in Alzheimer’s disease include granulovascular degeneration, Hirano bodies, β-amyloid deposition in the small cortical blood vessels, and neuronal loss in the limbic area.

Many biochemical abnormalities have been described in patients with Alzheimer’s disease. A decrease in the neurotransmitter acetylcholine is characteristic. Levels of the enzyme choline acetyltransferase, which synthesizes acetylcholine in the brain, can be reduced to 20% of that in age-matched control subjects. Several risk factors for Alzheimer’s disease are recognized, including advancing age, family history, low education level, hypercholesterolemia, and head trauma. The apolipoprotein E epsilon 4 allele on chromosome 19 has been associated with both familial and sporadic late-onset Alzheimer’s disease. Apolipoprotein E is responsible for transporting of the cholesterol and phospholipids necessary for dendritic and synaptic repair. There are several allelic variants, but those homozygous or heterozygous for the E4 variant have an increased risk for the development and expression of the disease. Abnormalities on chromosomes 1 and 14 also have been associated with Alzheimer’s disease.

The frontotemporal dementias are less prevalent than Alzheimer’s disease and are categorized by a frontal and temporal atrophy caused by cell death. The most common histologic finding in the frontotemporal dementias is the combination of prominent cell loss and gliosis in frontal and temporal regions of the cortex, termed dementia lacking distinctive histology. Approximately 15% to 20% of dementias are caused by multiple vascular insults to the CNS; the resulting deficit is termed multi-infarct dementia. The multiple infarcts typically involve the cerebral hemispheres and basal ganglia. Multi-infarct dementia often has an earlier age at onset than Alzheimer’s disease and occurs more often in adult men and patients who have risk factors for atherosclerosis. Approximately 29% of dementias are a mixed

**BOX 94.3**

**Diagnostic Criteria for Dementia**

A. Cognitive decline from a previous level of performance in one or more cognitive domains: complex attention, executive function, learning and memory, language, perceptual-motor function, or social cognition.
B. The disorder has an insidious onset and gradual progression.
C. The deficits do not occur exclusively during the course of a delirium.
D. The cognitive deficits are not better explained by another mental disorder, such as major depression or schizophrenia.

Inflammatory conditions of the CNS caused by conventional viruses include subacute sclerosing panencephalitis from measles virus infection, progressive multifocal leukoencephalopathy from infection by the John Cunningham (JC) virus (a papovavirus), progressive rubella encephalitis, and infection associated with HIV disease. The unconventional viral infections include kuru, Creutzfeldt-Jakob disease (CJD), and variant CJD (which appears to be linked to bovine spongiform encephalopathy, the pathologic process in “mad cow disease”) and are associated with minimal inflammatory histopathologic changes in the CNS; these diseases cause a fine vacuolation of the nervous tissue and hence are referred to as subacute spongiform viral encephalopathies.

Slow virus infections of the CNS can cause a progressive dementia that is irreversible. With these infections, months to years pass between infection with the virus and the appearance of clinical illness. Slow virus infections of the CNS are caused by both conventional viruses and unconventional virus like agents known as prions. A prion is a proteinaceous infectious particle with the apparent ability to start a chain reaction that changes the shape of benign protein molecules into abnormal, slowly destructive forms. Prions are present in CJD and variant CJD.

One of the most prevalent slow virus infections causing progressive dementia is HIV-1 infection. HIV may produce a primary neurotrophic disorder in addition to causing the immunologic compromise that permits other viruses to replicate and damage nervous tissue. HIV dementia or acquired immunodeficiency syndrome (AIDS) dementia complex occurs in approximately one-fourth of patients with AIDS. It is believed to be caused by the HIV-1 virus targeting the microglial cells and the macrophages, which may produce cytotoxic substances, such as tumor necrosis factor and interleukins. Pathologic changes occur mostly in the hippocampus and basal ganglia and include atrophy, ventricular dilation, and fibrosis.

Several of the potentially reversible causes of dementia also are associated with neuropathologic or neurochemical abnormalities. Normal-pressure hydrocephalus generally affects younger people; 50% of patients are younger than 60 years. Most of the conditions that cause hydrocephalus involve a defect in uptake of CSF by arachnoid villi, which results in gradual ventricular dilation.

Chronic, heavy ethanol consumption is associated with dementia. The neurotoxicity of ethanol appears to be independent of thiamine deficiency. Heavy chronic alcohol consumption causes cerebral cortical atrophy, but no single alcohol-related dementia syndrome exists.

Clinical Features

Family or friends usually bring the patient to the ED because of a sudden worsening in mental status, a change in the patient’s activities (eg, refusal to eat), or a change in the ability of the caregiver to manage the patient. Presentations vary by the cause of the dementia and the stage of progression. Many elders with dementia have a superimposed delirium on presentation.

The symptoms, signs, and progression of chronic cognitive impairment rarely are so diagnostic as to permit identification of the specific cause of the dementia. Alzheimer’s disease begins insidiously. Signs and symptoms of cognitive dysfunction may be present for months to years before the diagnosis is made. The earliest symptoms and signs of Alzheimer’s disease often are vague and nonspecific; patients manifest anxiety, depression, insomnia, frustration, and somatic complaints that often are more prominent than the memory loss. Patients often deny any cognitive deficits and change the subject of the conversation frequently rather than admit their increasing forgetfulness. Physicians often overlook the subtle signs of dementia in this phase of the disease. Various tests in the cognitive function can be used to improve the detection rate of subtle cases, document a change in their level of cognition or used to assist in determination of competency (see Table 94.2).

Depression often is the initial manifestation of Alzheimer’s disease and is present in up to 40% of cases. Early in the illness, short-term memory is affected with forgetfulness of recent events, such as appointments and names of new acquaintances. Patients often repeat questions. The memory impairment may cause them to withdraw from social situations and recreational pursuits. Attempts to perform complex tasks may produce anxiety and confusion. The patient often has difficulty with interpersonal relationships. Affect may be shallow and labile, and minor events may trigger inappropriate laughter or tears. Compensation for early deficits includes excessive orderliness and avoidance of situations in which the defects may be observed. Patients in this early phase who are treated with antidepressants with anticholinergic properties may experience worsening of their symptoms. Sedative-hypnotics prescribed for anxiety also may accelerate cognitive dysfunction.

As the dementia progresses, cognitive deficits are more obvious and should be readily apparent on a mental status examination. Problems with recent memory, impairment of remote memory, language deficits, and difficulty with spontaneous speech may be noted. With moderate severity of the disease, patients have difficulty naming objects (dysnomia). As many as 50% of patients have delusions, usually of the paranoid type. Atypical presentations of Alzheimer’s disease include aphasia, visual agnosia, right parietal lobe syndrome, focal neurologic findings, extrapyramidal signs, gait disturbances, and pure memory loss. In the final stage of dementia, patients exhibit marked cognitive impairment, apraxia, and significant personality changes. They often are bedridden and unable to perform the routine activities of daily living.

Because Pick’s disease dementia affects the frontal and temporal lobes, patients often have frontal lobe release signs, including dramatic behavioral changes of disinhibition and social inappropriateness. Basal ganglia degenerative disorders that have dementia as a prominent feature are Huntington’s chorea, Parkinson’s disease, and Wilson’s disease. One of several features that distinguish cortical from subcortical dementias is a prominent movement disorder, including posturing, ataxia, tremor, and chorea, that tends to occur early in the illness. Other features of these dementias include slowness of speech, hypotonia, and dysarthria, which can progress to mutism.

Patients with vascular dementia have a stepwise deterioration in memory and cognitive function with each cerebrovascular insult. The clinical presentation may follow one of two scenarios. In the more common scenario, the patient suffers several strokes that involve large volumes of cortical and subcortical structures in both hemispheres. The patient then exhibits dementia along with other neurologic disabilities (eg, focal weakness, hyperreflexia, extensor plantar response). In a second group of patients, the presentation is more subtle. These patients characteristically are hypertensive and suffer multiple tiny infarcts (lacunae) that involve deep subcortical structures. There may be no focal neurologic residua except progressive dementia with psychomotor retardation. Antihypertensive management in elders does not reduce the incidence of dementia.

The clinical manifestations of slow virus CNS infections are protean. After an insidious onset of mental deterioration in subacute sclerosing panencephalitis, a rapid progression ensues that is associated with myoclonic jerks, incoordination, and ataxia. In progressive multifocal leukoencephalopathy, neurologic signs and symptoms reflect diffuse asymmetrical involvement of both cerebral hemispheres. Sporadic CJD, of unknown etiology, tends to affect older people, with a rate of disease among those 50 to 70 years old of one case per million. Among these patients, rapidly...
evolving dementia with myoclonus is characteristic. The hallmark of the disorder are mental deterioration, multisystem neurologic signs, myoclonus, and typical electroencephalographic changes that evolve during months. Variant CJD affects younger patients (median age of 24 years) with key features that include early affective symptoms progressing to cognitive impairment and gait disturbances and ultimately leading to progressive neurologic deterioration. The incubation period appears to be in the range of 10 to 15 years, and most patients die within 14 months after the clinical onset of symptoms.

The classic triad of progressive dementia, ataxia, and urinary incontinence occurs in patients with normal-pressure hydrocephalus, which typically affects patients who are younger than those with primary degenerative dementia. More than half of the reported cases are in persons younger than 60 years old. Hydrocephalus secondary to previous head trauma or infection carries a more favorable prognosis than that for primary hydrocephalus.

In approximately 20% of the reversible cases, dementia is secondary to an intracranial mass. Patients may exhibit focal or nonfocal neurologic signs. Of the reversible dementias, 10% to 15% are caused by medications or chemical intoxications, frequently compounding a history of heavy alcohol use. Elders have increased susceptibility to the toxicities owing to polypharmacy and age-related changes in metabolism. The clinical presentation of a patient with a drug-related or toxin-related dementia may be indistinguishable from that of a patient with a primary degenerative process.

In addition, chronic traumatic encephalopathy (CTE) caused by repetitive mild traumatic brain injury and characterized by progressive neurodegeneration and deposition of hyperphosphorylated tau (p-tau) as neurofibrillary tangles may present as dementia and cognitive impairment. This form of encephalopathy develops 8 to 10 years after trauma and progresses to dementia, gait, and speech abnormalities and Parkinsonism. CTE may be clinically mistaken for Alzheimer’s disease or frontotemporal dementia.

**Differential Diagnosis**

**Senescent Forgetfulness**

Subacute or chronic cognitive decline may be caused by a dementing illness or can be a manifestation of senescent forgetfulness, delirium, or depression. Senescent forgetfulness is an almost inevitable reality of aging. Mild impairment of both short-term and long-term memory is usual. Unlike dementia, the cognitive disturbance in senescent forgetfulness does not interfere with work or customary social activity.

**Delirium**

In most cases, the clinical distinction between delirium and dementia is obvious (see Table 94.3). The onset of symptoms, progression of signs and symptoms, perceptual disturbances, abnormalities on assessment of vital signs, and fluctuations in the level of consciousness are key distinguishing features. However, dementia is a risk factor for delirium, and it is more difficult to differentiate delirium when superimposed on a patient with dementia.

**Depression**

Depression in older adults may closely mimic dementia. Diagnosis of pseudodementia or depression masquerading as dementia can be difficult and may require therapeutic interventions to confirm the clinical diagnosis. Confounding the issue, depression often coexists with dementia; one study found that 40% of patients with dementia were depressed. Depression, anxiety, and apathy are common in the prodrome and course of Alzheimer’s disease. A number of distinguishing features suggest that the problem is depression rather than dementia: the onset of cognitive changes in pseudodementia often can be pinpointed, and symptoms usually are of short duration before medical help is sought. The progression of symptoms is rapid, and the family usually is aware of the severity of the dysfunction. A history of psychiatric illness is common. Patients with pseudodementia usually complain of cognitive dysfunction and emphasize their failures and disabilities. The affective change often is pervasive, and the patient makes little effort to perform simple tasks. Loss of social skills usually occurs early in the illness, and patients communicate a strong sense of distress and inability to function. Intellectual functioning in pseudodementia often is difficult to assess because of lack of patient cooperation or inconsistent findings on neuropsychometric testing. Attention and concentration often are intact, but patients commonly give answers such as “I don’t know” on tests of orientation, concentration, and memory. Memory losses for recent and remote events usually are equally severe, and variability in the performance of tasks with similar degrees of difficulty may be marked. Tasks of high capacity (eg, testing of delayed memory with distraction) may be helpful in identifying the depressed patient.

**Diagnostic Strategies**

The evaluation of the patient with suspected dementia includes a focused medical, psychiatric, and medication history plus a collateral history from family and friends. Physical examination should include a detailed neurologic examination with a mental status evaluation. Dementia often goes unrecognized in the patient who is alert, pleasant, and cooperative. A validated cognitive evaluation test can play a key role in the early identification of dementia in patients who have maintained social and conversational ability.

**Cognitive Evaluation**

A mental status examination should be performed in all patients suspected to have cognitive dysfunction. In the demented patient, mental status testing can uncover subtle forms of delirium. Assessment of orientation to person, place, and time are not sensitive enough to establish cognitive dysfunction. A cognitive assessment should include both psychiatric and neurologic components (Box 94.4).

Several standardized tools for the cognitive assessment have been successfully applied in the ED. Mental status testing includes assessment of orientation, memory, attention, and concentration; several tests also incorporate assessments of constructional tasks,
spatial discrimination, arithmetic ability, and writing. Cognitive functioning can be rapidly assessed in approximately 7 to 10 minutes. Memory assessment requires testing of the patient’s ability to repeat short series of words or numbers (immediate recall), to learn new information (short-term memory), and to retrieve previously stored information (long-term memory). Constructional apraxia is assessed by having the patient perform tasks, such as drawing interlocking geometric figures or clock faces and connecting dots. Dysnomia (inability to name objects correctly) and dysgraphia (impaired writing ability) are two of the most sensitive indicators of delirium superimposed on dementia. Almost all acutely confused patients exhibit writing impairments, including spatial disorganization, misspelling, and tremor. Therefore, if patients screen positive for delirium the standardized tools cannot be used to assess for dementia.

No single bedside cognitive test that can be administered quickly is ideal. There are various tests of cognitive function, some of which have been tested in the ED (see Table 94.2). The MMSE developed by Folstein and colleagues has been validated more than any other test and most frequently is recommended as a rapid screening tool. For hospitalized patients, this test has a sensitivity of 87% and a specificity of 82% for detection of organic brain syndrome. The MMSE does not measure executive function and is insensitive for detection of early signs of mild cognitive impairment (without dementia) or early dementia.

The MMSE consists of a short series of questions that test orientation, registration (memory), attention, calculation, recall, and language scored on a 30-point scale. The time for the test to be administered can be reduced to 5 minutes by elimination of the writing and drawing components with only a modest reduction in sensitivity. The registration section tests both immediate and short-term memory; the recall section also assesses short-term memory. The ability to recall two of three objects has 81% sensitivity and 74% specificity for exclusion of organic brain syndrome. Asking the patient to subtract “serial sevens” backward from 100 assesses attention, concentration, and arithmetic ability. This test is specific but not sensitive for absence of an organic brain syndrome; up to 40% of nondelirious, nondemented people fail to perform the tasks of this test correctly, reflecting limitations due to language ability and education. A total score of 23 or less is considered markedly abnormal and indicates an organic brain syndrome. As a general rule, patients with mild cognitive impairment have a score of 18 to 26 out of 30, those with moderate impairment have a score of 10 to 18, and those with severe impairment have a score of less than 10.

Another frequently used test is the clock drawing test. It is scored on a 6-point scale from no errors to no reasonable representation of a clock. Patients with a score of 1 to 2 points are without impairment, and those with 3 to 6 points have cognitive impairment. All bedside tests of cognition have limitations and can miss mild degrees of impairment. The patient’s level of education and general intelligence can substantially affect the outcome. Furthermore, a single bedside test reflects a patient’s cognitive functioning at only one point in time.

Alzheimer’s disease is a clinical diagnosis typically made on probability; no routine available laboratory tests have been found to confirm the presence of the disorder (although MRI scan, functional scans looking at regional blood flow or glucose metabolism, assay for specific biomarkers, and CSF analysis can increase the probability of the presence of the disease). The physical examination is rarely helpful in detecting treatable dementias because of the considerable clinical overlap with irreversible dementias.

Laboratory Tests and Imaging Studies
Data clearly supporting or refuting the ordering of “routine” laboratory studies for evaluation of dementia are lacking; however, a number of studies are recommended to exclude treatable causes (see Box 94.2). For patients with suspected undiagnosed dementia presenting to the ED, a baseline laboratory evaluation, including CBC, comprehensive metabolic panel, and urinalysis, is indicated. If neurosyphilis is clinically suspected, a serum fluorescent treponemal antibody absorption test should be performed in addition to a Venerale Disease Research Laboratory (VDRL) test because the serum VDRL assay may yield negative results in patients with tertiary syphilis. The radiologic evaluation should include a non–contrast-enhanced head CT scan. The CT scan is used to diagnose or to exclude the presence of hydrocephalus or space-occupying lesions, and CT findings may support a vascular etiology for the dementia.

Patients require additional laboratory tests on follow-up evaluation; such tests may include determination of serum vitamin B₁₂ and folate levels, thyroid function studies, erythrocyte sedimentation rate, fluorescent antinuclear antibody assay, measurement of urine corticosteroid levels, and, if indicated by history, urine screens for drugs and heavy metals. Selected patients should undergo a LP with CSF analysis, MRI, positron emission tomography scan, electroencephalography (in CJD, characteristic slowing and periodic complexes may be electroencephalographic features), neuropsychological testing, and testing of visual evoked potentials, brainstem auditory evoked potentials, and somatosensory evoked potentials.

The EEG rarely is helpful in establishing the diagnosis of senile dementia. An MRI finding of medial temporal atrophy suggests Alzheimer’s disease but is not specific or sensitive for diagnosis of this disorder. Neuroimaging with head CT or MRI is controversial but indicated in patients with acute onset or rapid deterioration of cognitive impairment to identify rapidly progressive dementia and cerebrovascular accidents.

Summary
The diagnostic evaluation of the patient with suspected dementia includes a focused medical, psychiatric, and medication history, detailed neurologic and psychiatric examination with assessment of mental status and cognition followed by a baseline laboratory evaluation, including CBC, comprehensive metabolic panel, and urinalysis and non–contrast head CT. Additional evaluation should be guided by history and physical examination.

Mental status and cognitive assessment can be performed with several standardized tools that have been successfully applied in the ED. Initial mental status testing with the CAM may identify subtle forms of delirium. The CAM has four key features used in screening for delirium: (1) acute onset and fluctuating course, (2) inattention, (3) disorganized thinking, and (4) altered level of consciousness. For a definitive diagnosis of delirium, the first two features and one of the last two must be present. If the patient is CAM negative then further testing of cognition is warranted to identify dementia. The MMSE is a validated test of cognitive function that consists of a short series of questions that test orientation, registration (memory), attention, calculation, recall, and language. The clock drawing test is an alternate test of cognitive function that consists of a short series of questions that test orientation, registration (memory), attention, calculation, recall, and language. The clock drawing test is an alternate test of cognitive function that may be useful in the ED setting. All tests of mental status and cognition may be affected by the level of education and general intelligence and reflect a patient’s cognitive functioning at only one point in time. Patient’s identified with cognitive impairment in the ED should undergo further neuropsychiatric testing and treatment.

Management
Reversible dementias and conditions that cause worsening of baseline dementia require early diagnosis and treatment. Determination of reversible causes of dementia during the ED
evaluation occasionally is possible on the basis of the history (including medication history), physical examination, and head CT scan. Patients with acute changes in mental status or a relatively rapid onset of symptoms will require hospitalization for comprehensive evaluation. Patients presenting with recent gradual decline in cognitive function without an underlying acute medical condition can undergo further evaluation on an outpatient basis.

Pharmacotherapy approved by the U.S. Food and Drug Administration (FDA) for the treatment of mild to moderate Alzheimer’s disease includes the cholinesterase inhibitors donepezil (Aricept), rivastigmine (Exelon), and galantamine ( Razadyne). There are multiple randomized, placebo-controlled, large-scale clinical trials with these drugs establishing efficacy in improving cognitive functions and activities of daily living in patients with mild to moderate dementia. These drugs are not considered disease modifying, and there are limited data at present on the benefit of these drugs beyond 2 or 3 years (a significant number of patients discontinue medications because of side effects). The most common side effect of these agents is due to the cholinergic effects, including nausea, vomiting, and diarrhea.

In 2003, the FDA approved memantine (Namenda), a disease-modifying agent that helps regulate the excitatory effects of glutamate by antagonizing the N-methyl-D-aspartate receptor. Whether this drug alters the underlying disease process is unclear, but short-term studies show improved cognition in patients with moderate and moderate to severe Alzheimer’s disease. There are conflicting studies on the effectiveness of other agents, such as gingko biloba, vitamin E, nonsteroidal agents, and statins. Estrogen replacement is not indicated for cognitive improvement or maintenance in women with Alzheimer’s disease and can be detrimental. Ultimately, the key to altering the course of the disease is halting neuron loss. In severe dementia, the goal of management is supportive care.

Many therapies currently are under investigation for the modulation and early treatment of Alzheimer’s disease. These therapies include antibiotics (directed against Chlamydia pneumoniae), secretase modulators to reduce serum β-amyloid levels, immunization to reduce amyloid plaque burden, chelators to promote dissolution of β-amyloid, nonsteroidal anti-inflammatory medications, supplementation with omega-3 fatty acids, and testosterone.

Increasing evidence suggests that certain nonpharmacologic measures, including behavioral methods and avoidance of environmental triggers, may be effective in reducing agitation and anxiety in patients with dementia. On occasion, medications are needed for behavioral symptoms of dementia. Affected patients typically do not improve with anxiolytics. Adverse effects offset the modest advantages in the efficacy of antipsychotic drugs for the treatment of psychosis, aggression, or agitation in many patients with Alzheimer’s disease, and these drugs should be avoided when possible. However, despite the lack of consensus in the indication for use and dosages in older demented patients, butyrophenone (such as, haloperidol, 0.5 to 5 mg IM) or atypical antipsychotic olanzapine (2.5 to 5 mg IM) have been found to be effective in the management of acute agitation.

Clozapine may be effective in treating psychosis associated with both Alzheimer- and Parkinson-type dementias. However, in April 2005, the FDA issued a black box warning that the use of atypical antipsychotics to treat older patients with dementia related psychosis was associated with an increased risk for death compared with placebo, thus the risks and benefits of using these drugs must be considered.

A clear treatment choice for agitation and psychosis in those with dementia has not been identified. The antipsychotics raise a concern for QT prolongation, extrapyramidal symptoms, sedation, and anticholinergic and drug-drug interaction; the benzodiazepines have a fall risk, confusion, memory impairment, and oversedation. Regardless of intervention used, the lowest dose possible should be used and then titrated carefully to effect.

Agitation in patient with dementia may occasionally be due to unrecognized depression or pain. A trial of selective serotonin reuptake inhibitors (SSRIs) (such as, citalopram 20 mg PO) and adequate pain management may be warranted. Selection of a SSRI should be based upon side effect profile and drug interactions. Sleep disturbances may be treated with temazepam (7.5 mg oral), which is the drug of choice. The half-life of temazepam is 8 to 10 hours for patients of all ages, and the drug bypasses the oxidative hepatic enzyme system.

Disposition
Patients with dementia present to the ED because of an acute deterioration, behavioral change, or crisis due to family stress. A brief observation, acute inpatient medical or psychiatric hospitalization, nursing home stay, or other institutional stay (respite program) may stabilize patient and give the family time to mobilize resources to resume the home care regimen. Social workers can play a vital role in attempting to facilitate continued management. A key to successful disposition planning is to use screening tools to assess the cognitive, functional, and psychosocial status of patients with delirium and dementia. Anticipating and addressing cognitive or functional barriers to compliance with discharge plan and transitional care plan is essential.

**KEY CONCEPTS**

- Delirium is an acute condition characterized by an altered level of consciousness, disorganized thinking, and inattention. It develops during a short time, and symptoms tend to fluctuate during hours to days.
- Delirium is commonly caused by medications, drug intoxication or withdrawal, infections, metabolic disorders, CNS and cardiovascular events, and autonomic nervous system disturbances.
- Dementia is a chronic condition characterized by cognitive impairment. It is slow in onset and progressive in nature. This disorder has many causes, some of which are reversible with treatment. It is essential to search for reversible underlying etiologies that may be worsening a cognitive impairment.
- Patients with either dementia or psychiatric disorders may present with superimposed delirium, often making identification of the underlying cause of their abnormal behavior difficult.
- The clinician should be wary of attributing behavioral disturbances to psychiatric illness in the presence of abnormal vital signs or abnormal sensorium.
- Nonpharmacologic methods including behavioral methods and avoidance of environmental triggers should be considered in the treatment of agitation in patients with dementia.
- Antipsychotics and benzodiazepines are used cautiously, in the management of acute agitation in delirium and dementia. The choice of agent is determined by side effect profile and etiology of delirium or acute agitation.
- Antipsychotics and benzodiazepines are not approved for the long-term treatment of the behavioral symptoms of dementia.
- Antipsychotics may cause QTc prolongation and increased mortality especially when given intravenously.
- Lower doses of medications may be appropriate in older adults to decrease risk of adverse effects while effectively treating acute agitation.

CHAPTER 94: QUESTIONS & ANSWERS

94.1. Which of the following characteristics helps distinguish dementia from delirium?
A. Autonomic nervous system derangements
B. Cranial nerve dysfunction
C. Disorientation
D. Focal weakness
E. Pain

Answer: A. Delirium is characterized by a disturbance in level of consciousness with confusion. Demented patients present with a much more gradual onset of symptoms with typically no change in level of consciousness. Delirium is further characterized by autonomic nervous system abnormalities and the presence of an underlying disease process. The disturbance also tends to fluctuate in severity during the course of the day.

94.2. A 78-year-old woman presents with 3 days of decreasing ability to concentrate, memory and cognition breakdown, sleep cycle disruption, and fluctuating levels of agitation. Her current medications include levofloxacin (Levaquin) 500 mg/day for a bladder infection, tramadol prn for knee arthritis, and hydrochlorothiazide 25 mg/day for essential hypertension. Her examination is normal except for a baseline tachycardia, moderate agitation and restlessness, and orientation to person only. Laboratory analysis shows glucose 198 mg/dL, sodium 131 mEq/L, potassium 3.8 mEq/L, creatinine 1.4 mg/dL, white blood cell (WBC) count 11,300 cells/mm³, hemoglobin 12 g/dL, bicarbonate 25 mEq/L, and a normal urinalysis. What is the most likely etiology for her delirium?
A. Early sepsis
B. Hyperglycemia
C. Hyponatremia
D. Intracranial hemorrhage
E. Medication effect

Answer: E. Medications are the most common cause of delirium in the older adult population. Common inciting medications include antibiotics (quinolones and macrolides), analgesics, sympathomimetics, antiinflammatories, sedatives, and cardiovascular agents. This level of hyponatremia would not be expected to cause a delirium. Likewise, a modest hyperglycemia without associated acidosis would be an unlikely culprit.

94.3. An 82-year-old man presents with acute delirium. On examination, he is alert and mildly agitated. He is oriented to person and place but not time. He is easily distracted and exhibits a mild bilateral upper extremity resting tremor without asterixis. His neurologic examination is nonfocal. His short-term memory is impaired. What is the central component most key to the diagnosis of delirium in this case?
A. Agitation
B. Disorientation
C. Inattention
D. Memory dysfunction
E. Tremor

Answer: C. Disturbance in attention is central to the diagnosis of delirium. Disorientation often accompanies this but is not invariably present. The patient is usually disoriented to time and, less often, place. The delirious patient may also experience visual, auditory, tactile, and olfactory hallucinations; may lose the ability to modulate emotional expression; and often exhibits fluctuating symptoms. Short-term memory is usually impaired, but this is also seen in dementia.

94.4. Which of the following associations is correct?
A. Droperidol: QT prolongation
B. Haloperidol: Dysphoria
C. Lorazepam Excessive half-life
D. Meperidine: Cholinergic effects
E. Phentolamines: Hypocalcemia

Answer: A. This may also be seen, although less so, with haloperidol and the phentolamines. Meperidine causes dysphoria and possibly some anticholinergic effects. Diazepam results in the longest terminal Tₙ of the benzodiazepines.

94.5. A 63-year-old man presents with acute-onset delirium. He is a known alcoholic, and the family reports a cessation of alcohol intake 36 hours before presentation. He has no other known medical problems. Examination is remarkable for an acutely delirious patient who has active visual and auditory hallucinations and a mild tremor. Neurologic examination is otherwise negative, except for a left sixth cranial palsy. Finger-stick glucose is normal. Thiamine 100 mg intravenously fails to improve his symptoms. Which of the following is the intervention most likely to immediately improve his function?
A. Dextrose
B. Haloperidol
C. Lorazepam
D. Magnesium
E. More thiamine

Answer: D. Magnesium is a cofactor in the utilization of thiamine. In chronically magnesium-depleted patients, Wernicke’s encephalopathy may be refractory to thiamine until magnesium is also administered.
This chapter discusses cranial nerve (CN) problems, cerebral venous thrombosis (CVT), and multiple sclerosis (MS)—neurologic disorders that often provide diagnostic and therapeutic challenges in the emergency department (ED) setting (Table 95.1).

**TRIGEMINAL NEURALGIA (CRANIAL NERVE V)**

**Principles**

Trigeminal neuralgia, or tic douloureux, is a syndrome featuring painful paroxysms in one or more distributions of the trigeminal nerve (CN V). Trigeminal neuralgia is more common in women than in men, with a female-to-male ratio of 2:1. Affected persons typically are between 50 and 69 years old, and symptoms occur more frequently on the right side of the face.

Trigeminal neuralgia is an idiopathic disorder, although evidence points to vascular compression of the trigeminal nerve root in many cases. This compression commonly is caused by a tortuous arterial or venous loop in the posterior fossa, an arteriovenous malformation, or rarely a tumor. Although structural lesions are not found in all patients, surgical case series report up to 90% of cases having vascular compression of the trigeminal nerve root.

**Clinical Features**

Trigeminal neuralgia is manifested with unilateral facial pain, which is typically characterized as lancinating paroxysms of pain in the lips, teeth, gums, or chin. The pain is commonly associated with physical triggers, such as chewing, brushing the teeth, shaving, washing or touching the affected area of the face, swallowing, or exposure to hot or cold temperature in the affected area. The maxillary and mandibular divisions of the trigeminal nerve are most commonly involved; rarely, the ophthalmic division alone is involved. Patients tend to experience the pain in clustered episodes that last a few seconds to several minutes. The attacks can occur during the day or night but rarely arise during sleep.

The physical examination in patients with facial pain includes an evaluation of the sinuses, teeth, and the CNs. Given the location of the pain, the ears must be examined for signs of otitis, the teeth and face examined for evidence of odontogenic infection (such as, facial swelling or gingival fullness), and the skin and scalp examined for the painful vesicular eruption of zoster. Purulent drainage from the sinus indicates sinusitis as a possible underlying cause requiring treatment before continued pursuit of a diagnosis of trigeminal neuralgia.

**Differential Diagnosis**

Other painful facial conditions that are considered in patients with facial pain include odontogenic infections, sinus disease, otitis media, acute glaucoma, temporomandibular joint disease, and herpes zoster. Although the temporal components of the pain in these conditions are not similar to the sudden onset, lancinating pain of trigeminal neuralgia, the distribution is similar and these diagnoses should be considered before anchoring on a diagnosis of trigeminal neuralgia. Two percent to 4% of patients with trigeminal neuralgia also have MS, which should be considered in patients who present with neurologic findings that do not fit a specific pattern.

**Diagnostic Strategies**

Patients with normal findings on the head and neck examination and no neurologic deficits who have episodic, unilateral facial pain associated with nonpainful triggers are likely to have trigeminal neuralgia. The presence of a neurologic deficit should prompt suspicion of a structural lesion, such as aneurysm, tumor, or other intracranial lesion (eg, from MS). Patients with a neurologic deficit require urgent imaging studies, typically magnetic resonance imaging (MRI), to rule out a mass or vascular abnormality.

**Management**

The medical treatment of choice for trigeminal neuralgia is carbamazepine. The mechanism of action of anticonvulsant therapy for trigeminal neuralgia is unclear, but carbamazepine appears to be an effective and well-tolerated treatment. The initial dosage is 100 mg twice daily, increased to three times daily after 1 week. The dose may then be increased by 100 mg/day, up to a maximum of 1200 mg/day. A complete blood count and liver function studies are performed periodically in patients who are taking carbamazepine to monitor for hematologic and hepatic side effects. Additional agents that have been used for treatment of trigeminal neuralgia include phenytoin, baclofen, valproate sodium, lamotrigine, gabapentin, and levetiracetam. None has been shown to be more effective than carbamazepine. Several recent studies have investigated the use of onabotulinum toxin A for refractory pain management in trigeminal neuralgia. Although the studies are small, there are two randomized controlled trials that have shown decreased pain scores and increased quality of life with this therapy when combined with conventional medications.

Both peripheral and central surgical interventions for trigeminal neuralgia are management options for difficult cases. Peripheral strategies include medication injection and cryotherapy techniques designed to temporarily block or permanently ablate branches of the peripheral trigeminal nerve. Although these procedures are relatively effective initially, recurrence is common. Central procedures include percutaneous destruction of the trigeminal ganglion, although these procedures carry the risk of corneal anesthesia, oculomotor paresis, or masticatory weakness. Open surgical management includes microvascular decompression of the nerve with or without partial ablation. Although pain relief is achieved in 80% to 95% of patients, the surgery is associated with the risk of complications. Gamma knife radiosurgery, a minimally invasive, precision-directed stereotactic radiosurgery, has shown good outcomes.

</thead>
</table>
| CN I: Olfactory nerve | Sense of smell | Unilateral anosmia | Trauma: Skull fracture or shear injury interrupting olfactory fibers traversing the cribriform plate  
Tumor: Frontal lobe masses compressing the nerve |
| CN II: Optic nerve | Vision | Unilateral vision loss | Trauma: Traumatic optic neuropathy  
Tumor: Orbital compressive lesion  
Inflammatory: Optic neuritis (MS)  
Ischemic: Ischemic optic neuropathy |
| CN III: Oculomotor nerve | Extra oculomotor function via motor fibers to levator palpebrae, superior rectus, medial rectus, inferior rectus, inferior oblique muscles  
Pupillary constriction via parasympathetic fibers to constrictor pupillae and ciliary muscles | Ptosis caused by loss of levator palpebrae function  
Eye deviated laterally and down  
Diplopia  
Dilated, nonreactive pupil  
Loss of accommodation | Trauma: Herniation of the temporal lobe through the tentorial opening, causing compression and stretch injury to the nerve  
Ischemic: Especially in diabetes; microvascular ischemic injury to nerve causes extraocular muscle paralysis but usually is papillary sparing (often painful)  
Vascular: Intracranial aneurysms may press on the nerve, leading to dysfunction  
Myasthenia gravis can lead to atraumatic ocular muscle palsy |
| CN IV: Trochlear nerve | Motor supply to the superior oblique muscle | Inability to move eye downward and laterally  
Diplopia  
Patients tilt head toward unaffected eye to overcome inward rotation of affected eye | Trauma is the most common cause of nerve dysfunction |
| CN V: Trigeminal nerve | Motor supply to muscles of mastication and to tensor tympani  
Sensory to face, scalp, oral cavity (including tongue and teeth) | Partial facial anesthesia  
Episodic, lancinating facial pain associated with benign triggers, such as chewing, brushing teeth, light touch | Trauma: Facial bone fracture may injure one section, leading to area of facial anesthesia  
Tic douloureux |
| CN VI: Abducens nerve | Motor supply to the lateral rectus muscle | Inability to move affected eye laterally  
Diplopia on attempting lateral gaze | Tumor: Lesions in the cerebellopontine angle  
Any lesion, vascular or otherwise, in the cavernous sinus may compress nerve  
Elevated ICP: Because of its position and long intracranial length, increased ICP from any cause may lead to injury and dysfunction of the nerve |
| CN VII: Facial nerve | Motor supply to muscles of facial expression  
Parasympathetic stimulation of the lacrimal, submandibular, and sublingual glands  
Sensation to the ear canal and tympanic membrane | Hemifacial paresis:  
Lower motor neuron lesion leaves entire side of face paralyzed  
Upper motor neuron lesion leaves forehead musculature functioning Abnormal taste  
Sensory deficit around ear  
Intolerance to sudden loud noises | Lower motor neuron:  
Infection (viral): The likely cause of Bell’s palsy  
Lyme disease: The most common cause of bilateral CN VII palsy in areas where Lyme disease is endemic  
Bacterial infection extending from otitis media  
Upper motor neuron: Stroke, tumor |
| CN VIII: Vestibulocochlear nerve | Hearing and balance | Unilateral hearing loss  
Tinnitus  
Vertigo, unsteadiness | Tumor: Acoustic neuroma  
Mimics Ménière’s disease, perilymphatic fistula |
| CN IX: Glossopharyngeal nerve | General sensation to posterior third of tongue  
Taste for posterior third of tongue  
Motor supply to the stylopharyngeus | Clinical pathology referable to the nerve in isolation is very rare  
Occasionally painful paroxysms beginning in the throat and radiating down the side of the neck in front of the ear but behind the mandible | Brainstem lesion  
Glossopharyngeal neuralgia |

**Disposition**

Patients with newly suspected trigeminal neuralgia should be referred for specialty evaluation. Coordination with a neurologist will help in therapeutic decision making. Patients with an established diagnosis who present with uncontrolled pain refractory to maximum pharmacologic management may require a neurosurgical consultation for an operative intervention.

**FACIAL NERVE PARALYSIS (CRANIAL NERVE VII)**

**Principles**

Peripheral paralysis has no geographic, gender, or race predilection; pregnancy is a risk factor. The facial nerve (CN VII) innervates the muscles of facial expression and the muscles of the scalp and external ear in addition to the buccinator, platysma, stapedius, stylohyoid, and posterior belly of the digastic muscles. The sensory portion of the nerve supplies the anterior two-thirds of the tongue with taste and sensation to portions of the external auditory meatus, soft palate, and adjacent pharynx. The parasympathetic portion supplies secretomotor fibers for the submandibular, sublingual, lacrimal, nasal, and palatine glands. The nerve originates from the pontomedullary junction of the brainstem and enters the internal auditory meatus with CN VIII. Within the temporal bone, the facial nerve has four major branches: the greater and lesser superficial petrosal nerves, the nerve to the stapedius muscle, and the chorda tympani. The facial nerve exits the temporal bone at the stylomastoid foramen and then enters the parotid gland, where it divides to supply the muscles of facial expression.

**Clinical Features**

The medical history in patients with facial paralysis focuses on onset of the paralysis, concentrating on timing and rapidity of onset and associated signs and symptoms. The most common causes of a CN VII palsy are Bell’s palsy, Ramsay Hunt syndrome, Lyme disease, and bacterial infections of the middle ear, mastoid, or external auditory canal.

**Bell’s Palsy**

Bell’s palsy, also commonly called *idiopathic facial paralysis*, is postulated but not confirmed to have a viral cause. It is characterized by an abrupt onset of a lower motor neuron paresis that typically develops over 72 hours and can progress during 1 to 7 days to complete paralysis. A prodromal viral-like illness is described by 60% of patients. Symptoms and signs frequently associated with the facial paresis include ear pain, perception of sensory change on the involved side of the face, decreased tearing, overflow of tears on the cheek (epiphora), abnormally acute hearing (hyperacusis), and impairment or perversion of taste (dysgeusia).

To make the diagnosis of Bell’s palsy, both the upper and lower facial muscles must be involved. If only lower face involvement can be elicited, there should be a suspicion for a central lesion, such as a cerebral infarct or neoplasm. Lid closure is assessed by asking the patient to blink rapidly; if the patient is unable to fully close the eye, a diagnosis of Bell’s palsy suspected.

**Ramsay Hunt Syndrome**

Ramsay Hunt syndrome (herpes zoster oticus) is characterized by unilateral facial paralysis, a herpetiform vesicular eruption, and vestibulocochlear dysfunction. The vesicular eruption, which may follow the facial paralysis by a few days, may occur on the pinna, external auditory canal, tympanic membrane, soft palate, oral cavity, face, and neck as far down as the shoulder. The pain is considerably more severe than that associated with Bell’s palsy, and it frequently is out of proportion to physical findings. In addition, outcomes are worse than with Bell’s palsy, with a lower incidence of complete facial recovery and the possibility of sensorineural hearing loss.
Lyme Disease

Systemic symptoms or bilateral facial paresis, especially in endemic areas, should raise the possibility of Lyme disease. Lyme disease is the most frequent vector-borne infection in the United States. It is caused by the spirochete *Borrelia burgdorferi* and is spread by the bite of *Ixodes* genus ticks. Neurologic manifestations can arise in any phase of the disease, and facial palsy accounts for up to 50% of the neurologic presentations. In regions in which Lyme disease is endemic, it has been shown to be the leading cause of facial paralysis in children.

Bilateral facial nerve paralysis is rare but can occur with systemic infections. The two diseases most commonly associated with bilateral simultaneous onset of facial paralysis are Lyme disease and infectious mononucleosis. Bilateral facial paralysis should be considered to be a manifestation of Lyme disease until further testing excludes this diagnosis. The evaluation and treatment of Lyme disease are discussed in Chapter 126.

**Bacterial Ear Infections**

Facial paralysis can be caused by acute bacterial infections of the middle ear, mastoid, or external auditory canal. In the pre-antibiotic era, facial paralysis was associated with acute otitis media in approximately 2% of cases; today, however, it occurs in only 0.2% of cases. Malignant otitis externa can be associated with facial paralysis. This disease entity is most commonly seen in immunocompromised patients and usually is caused by *Pseudomonas* infection.

**Diagnostic Strategies**

The diagnostic evaluation of acute facial nerve paresis is based on whether the clinical picture is suggestive of a disease process other than Bell’s palsy. If the clinical history is classic for Bell’s palsy, the American Academy of Otolaryngology recommends no imaging or laboratory studies.6 A history that poses potential exposure to Lyme warrants serologic evaluation for the disease. Although outpatient testing including electroneurography may ultimately be performed, this usually is not part of the initial evaluation.

The presence of a “central” seventh nerve paralysis (upper face sparing) should prompt imaging with computed tomography (CT) or MRI, and consideration given to the possibility of an acute stroke or other hemispheric lesion. History or physical findings suggestive of a possible tumor require imaging to rule out a neoplasm. The study of choice will depend on the institution and preferences of the consultant but typically involves MRI.

**Management**

**Bell’s Palsy**

Both medical and surgical treatments of Bell’s palsy are available. The primary medical therapies for Bell’s palsy center on reducing inflammatory changes to the nerve with corticosteroids and treating the presumed viral cause. If these therapies are unsuccessful, surgical decompression may be considered.

Available evidence strongly favors the use of corticosteroids for the treatment of Bell’s palsy, and earlier treatment is associated with better outcomes.7,8 Steroid therapy is believed to inhibit edema of the nerve, confined within the facial canal, which is thought to cause or contribute to the nerve injury. Based on the results of high quality, randomized trials, we recommend treatment with prednisolone, 50 to 60 mg/day per day for 10 days, with or without a short taper. Therapy should be started as soon as possible, ideally within the first 24 hours, but it is still recommended for patients without contraindications who seek treatment within 1 week of symptom onset.

A number of studies have supported the contention that Bell’s palsy may be caused by herpes virus infection. Herpes simplex virus type 1 DNA has been demonstrated in the endoneurial tissue of Bell’s palsy patients, although there is conflicting evidence on the efficacy of antiviral treatment. Some studies have found treatment with corticosteroids plus antiviral medications to be superior to steroids alone, particularly in the setting of severe palsy or in those treated within 24 hours of symptom onset.10 Other studies have found conflicting results.10 Summary statements from the American Academy of Otolaryngology recommend that antivirals “be considered” in the treatment of Bell’s palsy, although they should only be offered in combination with oral steroids and should be considered more strongly for severe loss of function.10 We recommend valacyclovir, 1000 mg orally three times daily for 7 days, or famciclovir, 750 mg orally for 7 days (Table 95.2). Valacyclovir and famciclovir have better oral absorption, are better tolerated, and are closed less frequently, resulting in higher compliance than with acyclovir treatment. Although earlier treatment is preferred, treatment should be considered for patients presenting within 1 week of symptom onset.

**Ramsay Hunt Syndrome**

The treatment of Ramsay Hunt syndrome is similar to that of Bell’s palsy, although antiviral treatment is more strongly recommended in this disease process in addition to steroid therapy. Both prednisone and antiviral therapy should be continued for 7 to 10 days.

Lyme Disease

The treatment of Lyme disease is discussed in Chapter 126.

Bacterial Infections

Treatment bacterial infections causing a CN VII palsy involves prolonged intravenous (IV) antipseudomonal antibiotic therapy and may require surgical débridement.

Dispositional

Most patients who have a seventh CN paralysis will have a clinical diagnosis of Bell's palsy and may be discharged with referral for short-term follow-up. Patients with a possible hemispheric process, such as stroke or tumor, require further evaluation and often hospitalization. Patients thought to have Lyme disease require immediate initiation of antibiotic therapy.

In patients with a complete facial nerve paralysis and inability to close the eye, the ipsilateral eye should be patched. Patients should be advised of the risk for corneal abrasion and corneal dryness, which is associated with the inability to blink properly or to close the eye completely. Patients should be counselled regarding their expected timeline for recovery. Although mild paresis typically recovers within 2 to 3 weeks, complete paralysis may take up to 6 to 12 months for recovery. Patients with a complete facial nerve paralysis should be provided with an urgent referral to a head and neck surgeon.

VESTIBULAR SCHWANNOMA (CRANIAL NERVE VIII)

Principles

Vestibular schwannoma, formally referred to as acoustic neuroma, is a rare but important cause of sensorineural hearing loss. It occurs in middle-aged individuals and is usually unilateral in nature. Vestibular schwannoma is rarely bilateral, occurring in approximately 5% of cases and generally associated with type 2 neurofibromatosis. Although histologically benign, vestibular schwannoma can cause neurologic damage by direct compression on CN VIII and the other structures in the cerebellopontine angle.

Vestibular schwannomas arise from the Schwann cells covering the vestibular branch of the CN VIII as it passes through the internal auditory canal. The tumor may compress the cochlear (acoustic) branch of the CN VIII, causing hearing loss, tinnitus, and dysequilibrium. Continued growth of the tumor may result in compression of structures in the cerebellopontine angle, where CN V and CN VII may be compressed and damaged. Larger tumors may further encroach on the brainstem and, if large enough, may compress the fourth ventricle, ultimately resulting in signs of increased intracranial pressure (ICP).

Clinical Features

Asymmetrical sensorineural hearing loss is the hallmark of vestibular schwannoma. Up to 15% of patients with this tumor, however, will have normal results on audiometry. These patients typically have symptoms, such as unilateral tinnitus, imbalance, headache, fullness in the ear, otalgia, and facial nerve weakness. Thus, patients with asymmetrical symptoms should be further evaluated for vestibular schwannoma even with normal findings on audiometry.

Vestibular schwannomas are extremely slow-growing tumors, averaging an approximately 1-mm increase per year, although many do not grow at all. The median time from symptom onset to diagnosis is 12 months.

Differential Diagnosis

A majority of disease entities included in the differential diagnosis for vestibular schwannoma cause symmetrical sensorineural hearing loss. Asymmetrical sensorineural hearing loss has few causes other than vestibular schwannoma. Ménier’s disease may present with asymmetrical findings, but it can be differentiated from vestibular schwannoma in that the tinnitus of Ménier’s disease usually is intermittent, whereas the tinnitus of vestibular schwannoma typically is continuous. In addition, patients with Ménier’s disease typically describe true vertigo, whereas patients with a vestibular schwannoma are more likely to describe imbalance or dysequilibrium.

Vestibular schwannomas account for 80% of all cerebellopontine angle tumors, meningiomas are the second most common. Meningiomas more frequently cause symptoms of facial palsy or trigeminal nerve abnormality. Of note, however, considerable similarity between the clinical picture of a meningioma and that of vestibular schwannoma in the cerebellopontine angle has been described.

Diagnostic Strategies

When vestibular schwannoma is suspected, the patient is evaluated by audiometry or gadolinium-enhanced MRI. This imaging technique is extremely sensitive and has led to earlier diagnosis and a decrease in mean size at detection of vestibular schwannoma. CT lacks the necessary sensitivity in the posterior cranial fossa to reliably rule out the presence of vestibular schwannoma. The smaller the tumor at the time of diagnosis, the more options there are for therapy and the better the prognosis.

Management

Vestibular schwannoma may be removed surgically or ablated with stereotactic radiation therapy. In appropriately selected patients, there is little difference in long-term quality-of-life segregated by type of treatment.13 In general, tumors larger than 3 cm are recommended for microsurgery because radiation treatments, such as with the gamma knife, are less effective for local control and growth arrest in larger masses.14 Smaller tumors are amenable to use of stereotactic radiation therapy. Stereotactic radiation therapy generally has good long-term outcomes of local growth arrest, with nerve salvage approaching 90% or greater. In patients who are minimally symptomatic with small tumors, serial monitoring with MRI is a viable option.

Disposition

Patients with suspected acoustic neuroma should be referred for audiology or MRI and evaluation by a specialist in either otolaryngology or neurosurgery.

DIABETIC CRANIAL MONONEUROPATHY

Principles

Cranial mononeuropathies occur uncommonly, and usually are a complication of diabetes. They most often affect the extraocular muscles. The oculomotor nerve (CN III) is most commonly affected, followed by the trochlear (CN IV) and abducens (CN VI) nerves. CN palsies occur in 1% of diabetics versus 0.1% among nondiabetics. Whereas ophthalmoplegia appears to be closely related to diabetes, facial palsy is less strongly correlated with this disease.15

The pathologic basis of diabetic mononeuropathy appears to be ischemia caused by occlusion of an intraneural nutrient artery
serving the nerve. This occlusion leads to injury located primarily in the core fibers, whereas the peripheral nerve fibers are less affected because they also are supplied by collateral vessels. In the oculomotor nerve, the preservation of the circumferentially located parasympathetic fibers explains the pupillary sparing that usually is found in this syndrome.

Clinical Features

Patients typically describe acute onset of unilateral retro-ocular and supraorbital pain, diplopia, and ptosis. The physical manifestations of a CN III palsy include the inability to move the eye superiorly and medially, accompanied by ptosis. The pupillary light reflex usually is present. Although it is a less common finding, CN IV and CN VI may be affected. Patients with a CN IV palsy are unable to move the eye inferolaterally, and those with a CN VI palsy are unable to move the eye laterally. Because of the long intracranial course of CN VI, a patient with an isolated sixth nerve palsy should be evaluated for an intracranial lesion or increased ICP.

Differential Diagnosis

Diabetic mononeuropathy generally is a diagnosis of exclusion. Considerations in the differential diagnosis include trauma, tumor, vertebralbasilar ischemia, aneurysm, and brainstem hemorrhage.

Diagnostic Studies

Diagnostic imaging is not required in the setting of a “classic” oculomotor mononeuropathy. If a diabetic patient presents with an isolated CN III palsy with sparing of the pupillary light reflex in the absence of other CN or neurologic abnormalities, the diagnosis can be made presumptively. If the pupillary reflex is lost in the affected eye, one must be concerned about aneurysm and a computed tomographic angiogram (CTA) is indicated. If other CNs are involved or there are other acute neurologic deficits present, stroke remains a consideration and CT or MRI should be obtained. In a patient who presents with a cranial mononeuropathy but without a history of diabetes, a hemoglobin A1c might be helpful for the providers who assume care of the patient.

Management

Treatment consists of patching the affected eye and administration of analgesics and antiplatelet therapy. Although there is no specific cure, patient education regarding glucose control is important. The prognosis is good and the neuropathy generally resolves within 3 to 6 months. Antioxidant preparations, including α-lipoic acid, have been used therapeutically and have not shown harm, but such agents have yet to be shown to have convincing clinical effect.

CEREBRAL VENOUS THROMBOSIS

Principles

Cerebral blood is drained by several major veins that lead into the dural sinuses. The major dural sinuses are the superior sagittal sinus, the inferior sagittal sinus, the straight sinus, the lateral sinuses, and the sigmoid sinuses. The variability in symptoms and signs in patients who present with CVT stems from differences in thrombus location and acuity of thrombus formation. Women represent 60% to 75% of those diagnosed. The short-term mortality of CVT can be quite high, depending upon time to diagnosis and severity of neurological symptoms at the time of presentation. With early diagnosis and treatment, mortality rates are low.

Infectious causes of CVT include systemic infections and local infections, such as sinusitis, otitis media, and facial cellulitis. Noninfectious causes include direct injury to the cerebral venous system from trauma, surgery, dehydration, or any other conditions causing hypercoagulable states, including the presence of a malignant neoplasm or the use of oral contraceptive agents.

Clinical Features

Patients with CVT often present with symptoms of intracranial hypertension, especially headache; patients with CVT are more prone to hemorrhagic infarction and localizing neurologic deficits. Lethargy, seizures, decreased level of consciousness, or mental status changes may be noted. A patient’s symptom onset will vary in accordance with the extent of collateral vessel growth in the venous territory. Symptoms will appear only when the compensation for venous thrombosis is no longer sufficient or when hemorrhagic infarction occurs. Variability in collateralization between patients also adds to the variability and time course of symptoms. The average time from symptom onset to diagnosis of 7 days, reflecting the difficulty in diagnosis of this rare disease entity. Because of the broad spectrum of possible clinical features, the diagnosis of CVT may be difficult but should be a consideration in any patient with unexplained headache, especially in combination with focal neurologic deficit, papilledema, or seizures.

Patients with CVT will sometimes complain of diplopia or will be observed to have a dysconjugate gaze secondary to involvement of CN IV and CN VI. This can occur due to thrombosis of the cavernous sinus or simply from elevated ICP. In the presence of headache or a visual complaint, a funduscopic examination should be performed to look for papilledema, which is noted in up to 45% of patients with CVT.

Differential Diagnosis

The differential diagnosis of CVT is broad and includes the conditions that cause patients to present with the new onset of neurologic deficits, alteration in consciousness, or severe headache.

Diagnostic Strategies

Non-contrast CT scanning is commonly employed in the evaluation of patients with severe or unusual headaches, it is neither sensitive nor specific enough to reliably confirm or exclude the diagnosis of CVT. Findings on CT that are consistent with CVT include hyperdensity of a thrombosed sinus or deep vein (referred to as the cord sign or attenuated vein sign, respectively), brain edema, and hemorrhage secondary to venous congestion. MRI can demonstrate local changes secondary to venous congestion, such as brain edema and hemorrhage. In addition, MRI can demonstrate the possibility of CVT by the lack of a “flow void.” On conventional MRI, a flow void indicates the presence of moving blood within the sinus, whereas the absence of a flow void indicates a possible thrombus. Diagnostic accuracy, however, is greatly improved through use of magnetic resonance venography (MRV). This technique takes advantage of the MRI signal characteristics of flowing blood to create images of venous structures. Combination of these imaging techniques further enhances diagnostic accuracy. For imaging of a particular dural sinus, presence of the sinus on conventional MRI and lack of flow on MRV are diagnostic of a sinus thrombosis. This combined approach has diagnostic sensitivity similar to that of conventional angiography.

MRV and CT venography have similar sensitivities for the diagnosis of CVT when the CT study is performed on a multidetector row CT scanner; the sensitivity of CT venography for CVT approaches 100% and is comparable to that of MRV both in sensitivity and in inter-rater reliability. The sensitivity of CT
venography performed by scanners that do not use multidetector row technology is unknown. Based on the best available evidence, we recommend MRJ/MRV as the diagnostic study of choice when CVT is suspected, because this continues to be the gold standard against which all other diagnostic studies are compared.

D-dimer assays may have a role as a screening tool to exclude CVT, particularly when MRI or CT venography is not available. Although the reported sensitivity rates are fair at 83% to 100%, larger prospective studies are needed. In general, although a normal D-dimer level does not exclude the diagnosis of CVT, the diagnosis is much less likely, particularly in a patient with symptoms of less than 2 weeks in duration.

Management

CVT is a relatively rare disease, and controlled studies evaluating its treatment are lacking. Current therapeutic consensus strongly recommends systemic anticoagulation with low–molecular-weight heparin (LMWH) or unfractionated heparin to prevent further clot formation and to promote recanalization, even in patients with intracranial hemorrhage on initial imaging. A registry comparing outcomes of patients treated with unfractionated heparin compared with LMWH found more benefit in the LMWH group, although the effect was modest.16 Despite a paucity of randomized controlled trials, expert opinion favors anticoagulation in all groups unless another contraindication is present.

Catheter-based intervention with thrombolysis has shown promise in the management of CVT. Two case series have shown good outcomes in patients with altered mental status or coma at the time of presentation. All were treated in a non-randomized fashion with catheter-based thrombolysis with urokinase or tissue plasminogen activator (tPA), with 75% of patients recovering to a modified Rankin Scale of 0 or 1.17,18 This promising therapy is typically considered only for patients with symptoms of decreased level of consciousness, elevated ICP, or rapid neurologic deterioration.

Disposition

All patients with suspected CVT should be admitted to a unit capable of providing a high level of care with neurologic consultation. Patients should be anticoagulated if no contraindication exists, and catheter-based thrombolysis should be considered in patients with depressed mental status or focal findings on neurologic examination.

MULTIPLE SCLEROSIS

Principles

MS is an inflammatory disease that affects the central nervous system (CNS). The pathologic manifestation of this inflammatory disease is a demyelination of discrete regions (plaques) within the CNS with a relative sparing of axons. The clinical picture is highly variable, but it is classically characterized by episodes of neurologic dysfunction that evolve over days and resolve over weeks.

The peak age at onset is 25 to 30 years old; women are slightly younger than men at onset. The incidence in women exceeds that of men by a ratio of 1.8:1. MS is more common in temperate climates. The worldwide prevalence is greatest in the United Kingdom, Scandinavia, and North America. Epidemiologic studies indicate that both genetic and environmental factors are associated with an increased incidence of MS. It is rare in Africans and Asians, but African Americans have a higher incidence than their relatives who remain in Africa. Thus, an environmental cause superimposed on genetic susceptibility appears to be a likely etiologic scenario.

MS is considered to be an organ-specific autoimmune disease. One theory proposes that genetic factors interact with an environmental trigger or infection to establish pathologically autoreactive T cells in the CNS. After a long and variable latency period (typically 10 to 20 years), a systemic trigger, such as a viral infection or superantigen, activates these T cells. The activated T cells, on reexposure to the autoantigen, initiate the inflammatory response. This sets off a complex immunologic cascade that leads to the demyelination characteristic of MS. This demyelination process releases CNS antigens that are hypothesized to initiate further episodes of autoimmune-induced inflammation.

Clinical Features

The clinical picture in MS is one of marked heterogeneity. The classic clinical syndrome consists of recurring episodes of neurologic symptoms that rapidly evolve over days and slowly resolve over weeks. Variability occurs in age at onset, location of CNS lesions, frequency and severity of relapses, and degree and time course of progression.

The clinical features of MS can be divided into areas of specific CNS impairment: cognition; CNs; motor pathways; sensory pathways; cerebellar pathways; and bowel, bladder, and sexual dysfunction. Patients with MS have frequent complaints of poor memory, distractibility, and decreased capacity for sustained mental effort. Formal neuropsychological testing suggests that cognitive involvement is common and underreported, affecting up to 65% of patients. A correlation has been found between the MRI-based total lesion load and presence of cognitive impairment.

CN dysfunction is common in MS. The most common associated CN abnormality is optic neuritis, which is a unilateral syndrome characterized by pain in the eye and a variable degree of visual loss affecting primarily central vision. It is often the first symptom of MS. Within 2 years of an attack of optic neuritis, the risk of MS is approximately 20%, and within 15 years, it is approximately 45% to 80%.

As a result of lesions in the vestibulo-ocular connections, the oculomotor pathways also may be affected. The deficit may be manifested as diplopia or nystagmus. The nystagmus may be severe enough that the patient may complain of oscillopsia (a subjective oscillation of objects in the visual field). CN impairment also may include impairment of facial sensation, which is relatively common. Unilateral facial pain also may occur. In addition, the occurrence of trigeminal neuralgia in a young person may be an early sign of MS.

Motor pathways also are commonly involved; specifically, corticospinal tract dysfunction. Paraparesis or paraplegia occurs with greater frequency than upper extremity lesions owing to the common occurrence of lesions in the motor tracts of the spinal cord. In patients with significant motor weakness, spasm of the legs and trunk may occur on attempts to stand from a seated position. This dysfunction is manifested on physical examination as spasticity that typically is worse in the legs than in the arms. The deep tendon reflexes are markedly exaggerated, and sustained clonus may be demonstrated. Although these symptoms frequently are bilateral, they generally are asymmetrical.

Sensory manifestations are a frequent initial feature of MS and will be present in nearly all patients at some point during the course of the disease. Sensory symptoms are commonly described as numbness, tingling, “pins and needles” paresthesias, coldness, or a sensation of swelling of the limbs or trunk.

Impairment of the cerebellar pathway may result in gait imbalance, difficulty with coordinated actions, and dysarthria. Physical examination reveals the typical features of cerebellar dysfunction, including dysmetria, dysdiadochokinesia (an impairment of rapid alternating movements), breakdown in the ability to perform
complex movements, intention tremor in the limbs and head, truncal ataxia, and dysarthria.

Impairment of bowel, bladder, and sexual function also is common. The extent of sphincter and sexual dysfunction usually parallels the motor impairment in the lower extremities. Urinary frequency may progress to urinary incontinence as the disease advances. An atomic bladder may develop, which empties by simple overflow and often is associated with the loss of perception of bladder fullness and with anal and genital hypoesthesia. Constipation becomes common in time, and almost all patients with paraplegia require special measures to maintain effective bowel habits. Sexual dysfunction, although frequently overlooked, is common in MS. Approximately 50% of patients become completely sexually inactive as a result of this disease.

Differential Diagnosis

Other diseases that affect the CNS white matter may be clinically and radiographically similar to MS. These include CNS tumors (especially lymphomas and gliomas), spinal cord compression, vasculitides, Behçet’s disease, neurosarcoidosis, postinfectious and postvaccinal encephalomyelitis, human immunodeficiency virus (HIV) encephalopathy, Lyme disease, and vitamin B₁₂ deficiency.

Diagnostic Strategies

MS is a relapsing-remitting disorder with symptoms that fluctuate over time. Therefore, the clinical diagnosis rests on occurrence of at least two clinical episodes with different neurologic symptoms at different times.

Although no laboratory tests are diagnostic for MS, one clinical feature remains unique to this disease: Uhthoff’s phenomenon, temporary worsening of current or preexisting signs or symptoms of MS secondary to small increases in the patient’s body temperature. Accordingly, exercise, a hot bath, exposure to a warm environment, or fever can bring about Uhthoff’s phenomenon. This phenomenon reflects subclinical demyelination or preexisting injury to nerves without obvious significant clinical involvement before heat exposure or temperature elevation.

Lumbar puncture is recommended for evaluation of patients with suspected MS, but mass lesions and elevated ICP should be ruled out before lumbar puncture is attempted. CSF analysis is abnormal in 90% of the cases. Fifty percent of patients will have pleocytosis, with more than five lymphocytes per high-power field. Approximately 70% of patients will have an elevated gamma globulin level, with immunoglobulin G (IgG) ranging from 10% to 30% of the CSF total protein. Electrophoresis of the CSF demonstrates oligoclonal bands of IgG in 85% to 95% of patients who carry a diagnosis of MS; however, oligoclonal bands of IgG also are seen with neurosyphilis, fungal meningitis, and other CNS infections.

The initial imaging test to aid in the diagnosis of MS is gadolinium-enhanced MRI of the brain and spinal cord. MRI is a sensitive test for the detection of lesions consistent with MS and also is useful to assess disease severity. Lesions usually are multiple and commonly are found in the periventricular white matter. In patients with an initial neurologic event consistent with CNS demyelination and an MRI cranial study showing multiple white matter lesions, the 5-year risk for development of MS is 60%. Patients with similar clinical syndromes and a normal MRI appearance have less than a 5% risk.

Management

Management of patients with MS has essentially three aspects: (1) therapies aimed at halting the progression of the disease, (2) treatment of acute exacerbations, and (3) therapies designed to modify complications.

Treatment of Disease Progression

Although there are many therapies under development for treatment of early or established disease, standard therapies aimed at halting disease progression are based primarily on the use of either interferon-β or glatiramer acetate. The interferons are a group of natural compounds with antiviral and immunomodulatory actions used in therapy for MS. Side effects of the agents interferon-β₁a and interferon-β₁b include influenza-like symptoms, depression, anxiety, and confusion. Interferon-β₁a lowers relapse rate, prolongs time to first relapse, and lowers the accumulation of brain lesions on MRI. Interferon-β also has been shown to retard progression to clinically definite MS and to decrease the total number of brain lesions seen on subsequent MRI studies in patients who have their first demyelinating episode with MRI abnormalities at initial presentation. This finding highlights the importance of early evaluation and treatment.

Glatiramer acetate is a mixture of synthetic polypeptides designed to mimic myelin basic protein, which has successfully been used in the treatment of MS. The mechanism of action by which glatiramer acetate exerts its effect is unknown, but it is thought to modify the immune processes responsible for the pathogenesis of MS. Patients receiving glatiramer acetate experience significantly fewer relapses and are more likely to demonstrate neurologic improvement. It has also been shown to slow the progression to clinically definite MS after a first clinical demyelinating episode.

Current recommendations for management of relapsing-remitting MS are to initiate treatment with interferon-β or glatiramer acetate.¹⁹ Such regimens have been demonstrated to decrease the volume of plaques seen on MRI and to diminish relapses. Newer disease-modifying agents include fingolimod, laquinimod, daclizumab, natalizumab, and teriflunomide; their role is yet to be fully defined.

Treatment of Acute Exacerbations

Acute exacerbations of MS will generally resolve without therapy; however, steroids diminish the duration. More than 85% of patients with relapsing-remitting MS show improvement with IV methylprednisolone. IV steroids have been shown in controlled trials to speed the recovery from the visual loss of optic neuritis compared with placebo. In addition, when patients with acute optic neuritis are treated with high-dose IV steroids, the 2-year rate of development of MS is reduced, although this effect diminishes over time. Oral prednisone is not helpful and is associated with a potential increase in disease flares.

The current standard therapy for an acute exacerbation in MS is IV methylprednisolone, 250 to 500 mg every 12 hours for 3 to 7 days. Whether this should be followed by an oral prednisolone taper remains controversial. Potential adverse effects of methylprednisolone therapy include fluid retention, gastrointestinal hemorrhage, anxiety, psychosis, infection, and osteoporosis. Diagnostic diligence should be exercised in the evaluation of an acute exacerbation of MS, because many exacerbations are brought on by other medical issues, including infection. This is especially true of patients with severe preexisting disease.¹⁶

Treatment of Complications

Several therapies directed toward the complications of MS may be helpful. The associated spasticity generally is treated with
The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Facial sensation is intact. Corticosteroids are helpful, and they muscle paralysis), and external canal and pharyngeal numbness.

95.2. A 26-year-old man presents with complaints of left facial drooping. The symptoms began painlessly 3 days ago without a prodrome. Examination reveals a left facial droop with an inability to wrinkle the forehead without other associated physical examination abnormalities. Which of the following will provide the largest potential benefit to the patient’s recovery?
A. High-volume lumbar puncture
B. Initiation of oral antiviral treatments
C. Initiation of oral corticosteroids
D. Intravenous (IV) thrombolysis
E. Urgent non–contrast-enhanced computed tomography (CT) scan of the head

Answer: C. The patient has Bell’s palsy, which is a painless left facial nerve palsy. The primary symptom is a left peripheral nerve paralysis often with unilateral dysgeusia, hyperacusis (stapedius muscle paralysis), and external canal and pharyngeal numbness. Facial sensation is intact. Corticosteroids are helpful, and they should be initiated as far out as a week after onset, although they should be started within 24 hours if possible. Initiation of oral antiviral treatment has shown benefit in some trials, although conflicting evidence exists. In the absence of a contraindication and in a patient who can afford the medicine, antivirals should be considered. Given the classic picture and lack of other associated neurologic findings, CT scan of the head is not required and is not likely to provide benefit. Testing for Lyme disease is indicated in Lyme endemic areas or in patients with a history of a tick bite.

95.3. A 43-year-old woman presents with her fourth episode of left facial paralysis in 1 year. She denies prodrome or associated symptoms. Examination is consistent with an isolated left peripheral facial nerve paralysis. What should be the next step in her management?
A. Antinuclear antibody level and erythrocyte sedimentation rate
B. Carotid angiography
C. Initiation of antivirals and corticosteroids
D. Magnetic resonance imaging (MRI) scan
E. Neurology referral

Answer: D. A neoplastic cause should be suspected in patients who suffer from recurrent facial paralysis, significant pain, prolonged symptoms, or any associated cranial nerve (CN) dysfunction.

CHAPTER 95: QUESTIONS & ANSWERS
95.1. A 53-year-old woman presents with complaints of increasing left facial pain. She describes a pattern of brief, excruciatingly painful lancinating sensations along the left jaw associated with chewing and brushing her teeth. She notes intermittent clusters of pain that last seconds to a minute and have not occurred at night. Physical examination is normal except for triggered left jaw and buccal pain with palpation of the left mandibular area. What is the most likely finding in this patient?
A. Analgesia from a left inferior alveolar nerve block
B. Analgesia from subcutaneous sumatriptan
C. Immediate pain relief with high-flow oxygen
D. Magnetic resonance imaging (MRI) evidence of multiple sclerosis (MS)
E. Vascular compression of the trigeminal nucleus

Answer: E. In 80% to 90% of cases of trigeminal neuralgia, a vascular compression of the trigeminal nucleus is found in series of surgical cases. Microvascular decompression of the trigeminal nerve is curative in a high percentage of patients who fail to respond to medical management. Approximately 5% of patients with trigeminal neuralgia have MS. Cluster headache and migraine treatments are not effective. Peripheral nerve block is also ineffective because the pathologic process is more central at the nucleus.

95.2. A 26-year-old man presents with complaints of left facial drooping. The symptoms began painlessly 3 days ago without a prodrome. Examination reveals a left facial droop with an inability to wrinkle the forehead without other associated physical examination abnormalities. Which of the following will provide the largest potential benefit to the patient’s recovery?
A. High-volume lumbar puncture
B. Initiation of oral antiviral treatments
C. Initiation of oral corticosteroids
D. Intravenous (IV) thrombolysis
E. Urgent non–contrast-enhanced computed tomography (CT) scan of the head

Answer: C. The patient has Bell’s palsy, which is a painless left facial nerve palsy. The primary symptom is a left peripheral nerve paralysis often with unilateral dysgeusia, hyperacusis (stapedius muscle paralysis), and external canal and pharyngeal numbness. Facial sensation is intact. Corticosteroids are helpful, and they should be initiated as far out as a week after onset, although they should be started within 24 hours if possible. Initiation of oral antiviral treatment has shown benefit in some trials, although conflicting evidence exists. In the absence of a contraindication and in a patient who can afford the medicine, antivirals should be considered. Given the classic picture and lack of other associated neurologic findings, CT scan of the head is not required and is not likely to provide benefit. Testing for Lyme disease is indicated in Lyme endemic areas or in patients with a history of a tick bite.

95.3. A 43-year-old woman presents with her fourth episode of left facial paralysis in 1 year. She denies prodrome or associated symptoms. Examination is consistent with an isolated left peripheral facial nerve paralysis. What should be the next step in her management?
A. Antinuclear antibody level and erythrocyte sedimentation rate
B. Carotid angiography
C. Initiation of antivirals and corticosteroids
D. Magnetic resonance imaging (MRI) scan
E. Neurology referral

Answer: D. A neoplastic cause should be suspected in patients who suffer from recurrent facial paralysis, significant pain, prolonged symptoms, or any associated cranial nerve (CN) dysfunction.

95.4. Which of the following statements regarding acoustic neuroma is true?
A. An audiogram has a sensitivity of greater than 95%.
B. Gadolinium-enhanced magnetic resonance imaging (MRI) is the diagnostic test of choice.
C. Symptom onset is generally during years rather than months. Although increased ICP can happen, it is uncommon. The tinnitus of Ménière’s disease is typically intermittent rather than continuous.
95.5. Which of the following symptoms is not associated with diabetic cranial mononeuropathy?

A. Diplopia  
B. Inability to move the eye inferolaterally  
C. Nonreactive pupil  
D. Orbital pain  
E. Ptosis

Answer: C. Diabetic cranial mononeuropathy may affect the third, fourth, or sixth cranial nerve (CN). Pain, diplopia, and ptosis are common. Pupillary reactivity is usually preserved because these fibers are on the third nerve periphery and less affected by the occlusion of the “penetrating” neural nutrient artery affecting the core motor fibers. Inferolateral movement paralysis may be seen with a fourth nerve palsy and lateral paralysis with a sixth nerve palsy.

95.6. A 64-year-old diabetic woman presents with the acute onset of painless diplopia. She has a 25-year history of type 2 diabetes. Her only other past history is hypertension. Physical examination reveals normal vital signs and a normal neurologic examination with the exception of an inability to look laterally with the left eye. What is the most appropriate next step?

A. Cerebral angiography  
B. Contrast-enhanced computed tomography (CT) scan  
C. Magnetic resonance imaging (MRI) scan  
D. Ophthalmology consultation  
E. Patching the affected eye and initiation of antiplatelet therapy

Answer: C. Diabetic cranial mononeuropathy may affect the third, fourth, or sixth cranial nerve (CN). It is a diagnosis of exclusion, and brainstem ischemic or hemorrhagic lesions should also be considered. The long intracranial course of the sixth nerve makes MRI scanning particularly indicated to rule out a mass lesion. Once it is diagnosed, patching, analgesics, and antiplatelet therapy should be considered for management of this diabetic complication.

95.7. A 38-year-old woman presents 8 weeks postpartum with a 1-week history of severe headache and progressively altered mental status, which culminated in a seizure several minutes before presentation. On examination, she is normotensive, appears postictal, but has no focal neurologic findings. Ophthalmoscopic examination reveals papilledema, and non–contrast-enhanced head computed tomography (CT) reveals a dense sagittal sinus and a small venous hemorrhage in the occipital region. The next most appropriate management step is:

A. 325 mg aspirin per rectum  
B. Dexamethasone 10 mg IV push  
C. Hypertonic saline 500-mL bolus  
D. Mannitol 1 g/kg  
E. Systemic anticoagulation with unfractioned heparin or low–molecular-weight heparin (LMWH)

Answer: E. The patient presents with a dural sinus thrombosis. Although large, randomized trial data do not exist, case series and expert consensus strongly suggest improved outcomes with systemic anticoagulation, even in the setting of venous hemorrhage on head CT. Osmotic agents and steroids have no proven benefit in the management of sinus thrombosis and may cause harm. Antiplatelet agents may be considered if absolute contraindications to anticoagulation exist but probably have lower therapeutic efficacy.

95.8. A 20-year-old female college student presents with her third episode of bilateral foot numbness after a game of volleyball. Each episode has occurred approximately 1 or 2 hours after a full game of indoor volleyball, which she had no trouble completing. Each of the episodes of foot numbness resolved during 2 or 3 days with no residual symptoms. Her only other complaint is of falling grades in school due to subjective poor memory and distractibility. What would be the most likely finding in this patient?

A. Elevated cerebrospinal fluid (CSF) protein levels  
B. Elevated erythrocyte sedimentation rate  
C. Hypocalcemia  
D. Increased intracranial pressure (ICP) on lumbar puncture  
E. Thrombocytopenia

Answer: A. Presenting symptoms for multiple sclerosis (MS) may be myriad. Uhthoff’s phenomenon is the finding in MS in which small increases in body temperature exacerbate neurologic symptoms temporarily. Almost any neurologic complaint or finding may be a feature of MS, with up to 60% having cognitive impairment. CSF analysis is abnormal in 90% of cases with a pleocytosis and elevated protein with oligoclonal bands. ICP is normal. Lumbar puncture is undertaken after magnetic resonance imaging (MRI), which is the initial imaging test of choice.
PRINCIPLES

This chapter focuses on nontraumatic processes affecting the spinal cord and its vascular supply, as well as processes compressing the spinal cord. The ultimate neurologic outcome of patients with many of these disorders depends on expeditious recognition and management in the emergency department (ED).

Anatomy

In adults, the spinal cord is approximately 40 cm long and extends from the foramen magnum, where it is continuous with the medulla oblongata, to the body of the first or second lumbar vertebra. Like the brain, the spinal cord is covered by three meningeal layers: (1) the inner pial layer, (2) the arachnoid, and (3) the outer dural layer. At its lower end, the spinal cord tapers into the conus medullaris, where several segmental levels are represented in a small area. The lumbar and sacral nerve roots form the cauda equina as they descend caudally in the thecal sac before exiting the spinal canal at the respective foramina. The non-neural filum terminale runs from the tip of the conus and inserts into the dura at the level of the second sacral vertebra.

Two symmetrical enlargements of the spinal cord contain the segments that innervate the limbs. The cervical enlargement (cord level C5 to T1) gives rise to the brachial plexus and subsequently to the peripheral nerves of the upper extremity. The lumbar enlargement (L2 to S3) gives rise to the lumbar sac and peripheral nerves of the lower extremity. The space surrounding the spinal cord within the spinal canal is reduced in the area of the enlargements, potentially leaving the cord more vulnerable to compression in these regions. At each segmental level, anterior (ventral) and posterior (dorsal) roots arise from rootlets along the anterolateral and posterolateral surfaces of the cord. At each level, the anterior root conveys the outflow of the motor neurons in the anterior horn of the spinal cord, and the posterior root contains sensory neurons and fibers that convey sensory inflow.

The arterial supply of the spinal cord is derived primarily from two sources. The single anterior spinal artery arises from the paired vertebral arteries. This anterior spinal artery runs the entire length of the cord in the midline anterior median sulcus and supplies roughly the anterior two thirds of the spinal cord. Blood supply to the posterior third of the spinal cord is derived from the smaller paired posterior spinal arteries. The anterior and the posterior spinal arteries receive segmental contributions from radicular arteries, the largest being the radicular artery of Adamkiewicz, which typically originates from the aorta between T8 and L4. The venous drainage of the cord largely parallels the arterial supply.

For clinical purposes, neuroanatomy of the spinal cord may be greatly simplified, as depicted in Figure 96.1. Tracts are named with the point of origin first; the spinothalamic tract, for example, arises in the spinal cord and travels to the thalamus. Major ascending sensory tracts are represented on the right side of the figure, with motor tracts on the left side. The posterior columns carry afferent ascending proprioceptive and vibratory information on the ipsilateral side of the cord to the area stimulated; decussation of these fibers occurs in the medulla so that contralateral cortical representation is consistent. The lateral spinothalamic tract conveys afferent information about pain and temperature in a portion of the lateral column of white matter. The tract is laminated so that sacral fibers are represented most laterally. Crossing of fibers from this tract occurs near the level of entry of the spinal nerve; a cord lesion affecting only one lateral spinothalamic tract results in decreased or absent pain and temperature perception below the level of injury on the contralateral side of the body.

For clinical purposes, the major descending motor tract is represented in the lateral corticospinal tract (which, as the name implies, originates in the cortex and descends to the spinal cord). This tract also is anatomically organized, with efferent motor axons to the cervical area located medially and the sacral efferent axons located laterally. Decussation of this descending tract occurs in the medulla. The cell bodies of the lower motor neurons (antior horn cells) are in the ventral (anterior) portion of the gray matter of the spinal cord.

Classification of Spinal Cord Syndromes

The anatomic organization of the spinal cord lends itself to a corresponding anatomic-pathophysiologic classification of cord dysfunction. Any of the different anatomic syndromes may be the final clinical picture of a variety of clinical processes. The syndromes frequently exist in partial or incomplete forms, adding to the diagnostic challenge.

Complete (Transverse) Spinal Cord Syndrome

Complete spinal cord lesions may be manifested as either acute or subacute pathologic processes. A complete spinal cord lesion is defined as a total loss of sensory, autonomic, and voluntary motor innervation distal to the spinal cord level of injury. Reflex responses mediated at the spinal level, such as muscle stretch (deep tendon) reflexes, may persist, although they also may be absent or abnormal. Autonomic dysfunction may be manifested acutely with hypotension (neurogenic shock) or priapism. The most common cause of the complete transverse cord syndrome is trauma, although this anatomic syndrome may apply to any pathologic etiology. Other causes of acute complete cord syndrome include infarction, hemorrhage, and entities causing extrinsic compression. In patients with acute complete transverse syndromes that persist for more than 24 hours, functional recovery almost never occurs. Any evidence of preserved cord function below the level of injury denotes a partial rather than a complete lesion. Signs
Incomplete Spinal Cord Lesions

Incomplete spinal lesions are characterized by preservation of function of various portions of the spinal cord. Of all incomplete spinal lesions, most can be classified generally as one of three clinical syndromes: (1) central cord syndrome, (2) Brown-Séquard syndrome, or (3) anterior cord syndrome (Table 96.1).

Central Cord Syndrome. Central cord syndrome is the most common of the partial cord syndromes. Because of the anatomic organization of the spinal cord, a central cord injury is characterized by bilateral motor paresis; upper extremities are most affected. This injury often occurs in elders with degenerative arthritis and spinal stenosis in the cervical area but may affect any patient with cervical canal narrowing of any etiology (eg, congenital narrow canal as seen in achondroplasia or acquired canal narrowing from disk protrusion or tumor). The prognosis with central cord syndrome depends on the degree of injury at presentation and the patient’s age, with older age predicting a decreased functional outcome. In patients younger than 50 years old, more than 80% regain bladder continence and approximately 90% return to full ambulatory status. In patients older than 50 years old, only 30% regain bladder function and approximately 50% regain the ability to ambulate.

Brown-Séquard Syndrome. Brown-Séquard syndrome is the result of an anatomic or functional hemisection of the spinal cord. Usually associated with penetrating injuries, Brown-Séquard syndrome also may be seen with compressive or intrinsic lesions. The syndrome has been reported in association with spinal cord tumors, spinal epidural hematoma, vascular malformations, cervical spondylosis, degenerative disk disease, herpes zoster myelitis, and radiation injury and as a complication of spinal instrumentation. The syndrome in its pure form is characterized by ipsilateral loss of motor function and proprioception or vibration, with contralateral loss of pain and temperature sensation below the spinal cord level of injury. Because fibers associated with the lateral spinothalamic tract ascend or descend one or two spinal cord segments before crossing to the contralateral side, ipsilateral anesthesia (pain and temperature modalities) may be noted one or two segments above the lesion, although this observation is variable. Most patients with Brown-Séquard syndrome incur only partial sensory and motor impairment, and the classic pattern is not seen. Brown-Séquard syndrome carries the best prognosis of any of the incomplete spinal cord syndromes. Fully 80% to 90% of patients with Brown-Séquard syndrome regain bowel and bladder function, 75% regain ambulatory status, and 70% become independent in their activities of daily living.

Anterior Cord Syndrome. Anterior cord syndrome is characterized by loss of motor function, pinprick, and light touch below the level of the lesion with preservation of posterior column modalities, including some touch, position, and vibratory sensation. Although most reported cases of anterior spinal cord syndrome follow aortic surgery, the syndrome also may occur after severe hypotension, infection, myocardial infarction, vasospasm from drug reaction, and aortic angiography. The anatomic lesion may be caused by a cervical hyperflexion injury resulting in a cord contusion or by protrusion of bone fragments or herniated cervical disk material into the spinal canal. Rarely, it is produced by laceration or thrombosis of the anterior spinal artery or a major radicular feeding vessel.

Patients present with characteristic mixed motor and sensory neurologic findings. Functional recovery varies; most improvement occurs during the first 24 hours, but little improvement is expected thereafter. Although anterior cord lesions from ischemia usually are incomplete, patients without motor function at 30 days have little or no likelihood of regaining any motor function by 1 year. Overall, only 10% to 20% of patients with this entity regain some muscle function, and even in this group there is little power or coordination.

Conus Medullaris and Cauda Equina Syndromes

The separation of conus medullaris and cauda equina lesions in clinical practice is difficult because the clinical features of the disorders overlap. In addition, a combined lesion may occur that masks clear clinical symptoms or signs of either an upper or a lower motor neuron type of injury. The conus medullaris is the terminal end of the spinal cord, located at approximately the L1 level in adults.
The cauda equina (Latin for “horse’s tail”) is the name given to the lumbar and sacral nerve roots that continue on within the dural sac caudal to the conus medullaris. Not a true “cord syndrome,” cauda equina syndrome represents dysfunction at the level of nerve roots, but the anatomic clustering of nerve roots within the lumbar dural sac allows injury to several nerve roots to occur simultaneously.

The etiologic lesion in the cauda equina syndrome usually is a midline rupture of an intervertebral disk, most commonly at the L4 to L5 level. Tumors and other compressive masses also may cause the syndrome. As in the conus medullaris syndrome, patients generally present with progressive symptoms of fecal or urinary incontinence, impotence, distal motor weakness, and sensory loss in a saddle distribution. Muscle stretch reflexes also may be reduced. Urinary retention is the most consistent finding, with a
sensitivity of 90%. A complaint of low back pain may or may not be present with cauda equina syndrome.

**CLINICAL FEATURES**

**History**

Weakness, sensory abnormalities, and autonomic dysfunction are the cardinal manifestations of spinal cord dysfunction. The tempo and degree of impairment often reflect the disease process. Past medical history is vital because a history of coagulopathy or other systemic processes may be elicited. A history of cancer should suggest the possibility of metastatic disease. Recent trauma raises the possibility of vertebral fracture or disk protrusion. The acuity of pain may help narrow the differential diagnosis. Sudden immediate pain or dysfunction is more likely to be a vascular catastrophe, whereas slower onset, midline location, and historical presence of fever points toward an infectious source.

**Physical Examination**

The physical examination pertinent to spinal cord dysfunction involves testing in three areas: (1) motor function, (2) sensory function, and (3) reflexes. Each component is best tested with the anatomic organization of the spinal cord in mind to help determine the level of the spinal cord dysfunction.

**Motor Function**

Testing of motor function encompasses examination of muscle bulk, tone, and strength. Muscle bulk is easily examined in large motor groups, such as the thigh or calf muscles, the biceps, and the triceps. Inspection of the intrinsic hand muscles also may be helpful for determination of muscle bulk; wasting may be evident as hollowed or recessed regions of the hand. Decreased mass, asymmetry, or fasciculations should be noted. Tone is tested with repeated passive knee, elbow, or wrist flexion, with the examiner assessing for abnormally increased or decreased resistance. Rapid pronation-supination of the forearm is another useful method to check tone. Increased tone may indicate spasticity or an upper motor neuron lesion, whereas decreased tone corresponds with lower motor neuron, motor end-plate, or muscle problems. Finally, motor strength is graded in the upper and the lower extremities. Motor grading for the neurologic examination is relatively straightforward. Note that a tremendous gradient of strength is within the fourth grade of the scale. Scored on a scale of 0 to 5, neuromuscular functioning is graded as shown in Table 96.2.

A rectal examination and the bulbocavernosus reflex are performed to assess voluntary sphincter contraction, and resting tone. Although it is not commonly thought of as a physical examination maneuver, a post-void residual urine volume is useful to evaluate bladder function. A post-void residual volume of more than 100 to 200 mL in a patient without prior voiding difficulty might suggest bladder dysfunction of neurologic cause.

**Sensory Function**

Sensory testing requires a cooperative patient and an attentive examiner. The spinal cord–related modalities that may be clinically useful include testing for pinprick and light touch (contralateral lateral spinothalamic tract) and proprioception (ipsilateral posterior column). Assessment of the patient’s response to pinprick, light touch, and proprioception in all four extremities is necessary if a neurologic injury is suspected. Testing of sacral dermatomes is indicated in patients with suspected cord injury in that sacral sparing suggests that spinal cord dysfunction may be incomplete. The sensory fibers from sacral dermatomes are more peripherally located in the ascending fiber bundles; central or partial cord lesions may ablate sensation in the extremities yet allow some perception of sensation in the sacral area.

**Reflexes**

Muscle stretch (deep tendon) reflexes are graded on a scale of 0 to 4+, with 2 being normal. Hyperactive reflexes suggest upper motor neuron disease (affecting the neurons or their outflow from the brain or spinal cord), as do sustained clonus and Babinski’s sign. If present, hyperactive or abnormally brisk reflexes may be a key finding suggesting a myelopathy. However, absence of hyperreflexia does not exclude a myelopathy. Reflexes may be diminished or absent when sensation is lost or when spinal shock is present. Diseases of muscles or neuromuscular junctions also may decrease reflexes. In acute cord injury, reflexes may be diminished in the acute phase. The bulbocavernous reflex may be helpful in this assessment.

**DIFFERENTIAL DIAGNOSIS**

The prime principle in management of spinal cord dysfunction is to consider and exclude potentially treatable clinical conditions. The clinician should rule out any nonstructural cause of neurologic dysfunction (eg, hypoglycemia, hypokalemia) early in the evaluation process. The next step, once a neurologic entity is suspected, is to try to differentiate the location of the lesion (brain versus spinal cord versus motor end-plate). When the pathologic process is suspected to be spinal in origin, liberal use of consultation and imaging is recommended. Spinal cord diseases may mimic many other disease processes, and neither the history nor physical examination may allow diagnosis until appreciable neurologic dysfunction has developed.

The picture of a complete transverse spinal cord syndrome with paraplegia, sensory loss at a clear anatomic level, and sphincter dysfunction cannot be fully simulated by other anatomic lesions. Incomplete or evolving spinal cord syndromes may be imitated by other disease processes. Ataxia may be a finding in cerebellar disease but also has rarely been reported as an isolated finding with spinal cord compression. Another example is rapidly progressive paralysis in a patient with areflexia and quadriplegia; ascending paralysis (Landry-Guillain-Barré syndrome) at times may mimic an acute cord lesion.

In general, pathologic processes involving the spinal cord may be divided into processes affecting the cord or its blood supply primarily, such as demyelination, infection, or infarction, and processes that compress the cord, most often originating outside the dura (see Table 96.2). Myelitis is a comprehensive term for spinal cord inflammation with dysfunction, and the potential causes are
Steroid administration had been traditionally recommended as therapy in spinal cord trauma, although the benefit has been seriously questioned (Chapter 36). Steroids have also been used with many nontraumatic causes of cord compression despite the lack of rigorous clinical studies supporting this use (Box 96.1). Based on available evidence, we cannot recommend the use of steroids for the acute management of spinal cord compression syndromes. Radiation treatment is recommended for cord compression by tumor. Surgical consultation for decompression may be considered, although the indications and timing for surgery are controversial.

**Specific Disease Processes**

Spinal cord disorders are grouped into lesions resulting from processes intrinsic to the cord or vasculature and lesions causing extrinsic compression (see Table 96.2).
Intrinsic Cord Lesions

Multiple Sclerosis

Demyelination denotes a disease process with the prominent feature of partial or complete loss of the myelin surrounding the axons of the CNS. MS is the most common example of such a process; spinal cord involvement may dominate the clinical picture. The spinal cord will be involved with MS in as many as 90% of patients. In as many as 20% of patients with MS, the spinal cord lesions will be the only area where plaques are identified (Fig. 96.3). The pathophysiology, diagnosis, and management of MS is discussed in Chapter 95.

Transverse Myelitis

Principles. Acute transverse myelitis refers to acute or subacute spinal cord dysfunction characterized by paraplegia, a transverse level of sensory impairment, and sphincter disturbance. It describes a heterogeneous group of inflammatory disease processes that can affect the spinal cord by interruption of the ascending or descending pathways in the spinal cord. The presentation may be mimicked by compressive lesions, trauma, infection, or malignant infiltration.

The pathogenesis of transverse myelitis is unknown, although it is noted to follow viral infection in approximately 30% of patients and commonly is termed postinfectious myelitis. Other postulated etiologic categories include infectious, autoimmune, and idiopathic. It can also be seen with a wide variety of connective tissue diseases, such as lupus, Sjögren's syndrome, antiphospholipid syndrome, and other mixed-connective tissue diseases. No apparent cause of acute transverse myelitis is identified in 30% of the patients. Progression of symptoms usually is rapid, with 66% of the cases reaching maximal deficit by 24 hours. Symptoms may progress, however, over days to weeks. The thoracic cord is rarely affected.

Clinical Features. In addition to motor, sensory, and urinary disturbances, patients with acute transverse myelitis may complain of back pain and may have low-grade fever, raising concern for spinal epidural abscess (SEA). As with MS, the examination may reveal weakness progressing to paresis, hypotonia, hyperreflexia, clonus, and Babinski's response. Spinal cord involvement also can result in dysautonomias (ie, dysfunction of the autonomic nervous system).

Differential Diagnosis. Considerations in the differential diagnosis for transverse myelitis include MS, SEA or hematoma, primary or metastatic spinal neoplasm, and spinal cord infarct.

Diagnostic Strategies. MRI with gadolinium enhancement is the diagnostic modality of choice for patients with suspected transverse myelitis. In cases of diagnostic uncertainty, a lumbar puncture may be performed; however, the results of CSF studies are normal in 40% of cases, with only mildly elevated protein level or pleocytosis in the remaining 60%. The most essential aspect of the evaluation is to eliminate a potentially treatable cause, such as SEA, neoplasm, or hematoma.

Management. Treatment of transverse myelitis is tailored to the suspected underlying etiology. There are no good studies supporting a role for steroids. Neurologic consultation is suggested, and hospitalization usually is required.

The clinical course of acute transverse myelitis varies widely, ranging from complete recovery to death from progressive neurologic compromise. Most patients with idiopathic disease have at least partial recovery, which usually begins within 1 to 3 months. Maximal improvement usually is obtained within 3 to 6 months with 30% of patients having a good recovery, 25% a fair recovery, and 30% a poor outcome; there is 15% mortality at 5 years.

Spinal Subarachnoid Hemorrhage

Principles. Intraspinal hemorrhage is rare and may occur in the same anatomic locations as intracranial hemorrhages; epidural, subdural, subarachnoid, and intramedullary hemorrhages are all possible. Spinal subarachnoid hemorrhage usually is caused by an arteriovenous malformation. Hemorrhage from tumors or cavernous angiomas and spontaneous hemorrhage secondary to anticoagulation therapy also have been reported. Bleeding may occur exclusively in the subarachnoid space or within the substance of the spinal cord itself.

Clinical Features. Patients with spinal subarachnoid hemorrhage present with excruciating back pain of sudden and severe onset at the level of the hemorrhage. This pain also may be in a radicular distribution or extend into the flank. Patients may complain of headache and exhibit cervical rigidity if the blood migrates into the intracranial subarachnoid space, simulating an intracranial subarachnoid hemorrhage. Variable neurologic deficits depend on the magnitude and anatomic location of the...
hemorrhage. These deficits typically include extremity numbness, weakness, and sphincter dysfunction. Nuchal rigidity or signs of meningeal irritation may also be present. Although this is a rare etiology, when the back pain or neurologic dysfunction is sudden in onset, spinal hemorrhage should be considered.

**Differential Diagnosis.** Considerations in the differential diagnosis include epidural abscess, tumor, transverse myelitis, ischemia from aortic dissection, and anterior spinal artery thrombosis.

**Diagnostic Testing.** Because bone artifact may obscure presence of blood in the spine, the diagnostic study of choice in patients with suspected spinal subarachnoid hemorrhage is a MRI without contrast. Lumbar puncture also can confirm the presence of blood in the CSF. Angiography may be recommended if arteriovenous malformation is suspected.

**Management.** The treatment of spinal subarachnoid hemorrhage depends on the etiology of the hemorrhage. Neurosurgical referral is obtained for further evaluation and for clot evacuation if compression is present.

### Syringomyelia

**Principles.** Syringomyelia is the presence of a cavitary lesion within the substance of the spinal cord. A syrinx usually is a chronic progressive lesion, and its location within the cord determines the constellation of neurologic findings on examination. Ninety percent of patients with syringomyelia have Arnold-Chiari I malformation (projection of cerebellar tonsils and medulla into the spinal canal). Syringomyelia also may result from spinal cord trauma (often months to years later) or compressive tumors, or it may follow meningitis.

**Clinical Features.** Headache and neck pain are the most common presenting complaints of patients with a syrinx, followed by sensory disturbance, gait disorder, and lower cranial nerve dysfunction. Symptoms may be exacerbated by a sneeze, cough, or Valsalva maneuver. The symptoms of syringomyelia develop and progress in accordance with the intracavitary pressure and location of the syrinx.

The most common features on physical examination are lower limb hyperreflexia, weakness and wasting in the hands and arms, dissociated sensory loss, and gait disorder. The classic pattern of sensory deficit involves a loss of pain and temperature sensation in the upper extremities with preservation of proprioception and light touch. This phenomenon is described as a “dissociative anesthesia” because of the discrepant loss of sensory modalities. The sensory deficit often is described as being in a “capelike” distribution over the shoulders and arms. The anatomic basis for the neurologic features of a syrinx is the location near the central canal. Crossing fibers of the lateral spinothalamic tract carrying pain and temperature fibers may be impaired. Crude touch, position, and vibratory sensation typically are unaffected. Sensory fibers from the lower limbs are similarly spared.

**Differential Diagnosis.** Considerations in the differential diagnosis for syrinx include intrinsic spinal tumor and demyelination.

**Diagnostic Testing.** Syringomyelia is best seen on MRI. No other study currently in widespread use is equal to MRI in diagnostic ability.

**Management.** When the diagnosis of syringomyelia is considered, emergent imaging in the ED is not necessary if follow-up evaluation can be arranged; in approximately two thirds of patients this condition is a slowly progressive process. In patients for whom MRI studies are obtained and the diagnosis is made, referral to a neurosurgeon is indicated.

### Human Immunodeficiency Virus Myelopathy

Human immunodeficiency virus (HIV) myelopathy typically occurs in patients with advanced disease. Weakness, gait disturbance, sphincter dysfunction, sensory abnormalities, and signs of spasticity are features of this progressive process. This is a diagnosis of exclusion because disorders such as toxoplasmosis, lymphoma, varicella-zoster, and cytomegalovirus infection may produce a similar clinical picture in immunocompromised patients. On pathologic examination, vacuolization of myelin sheaths in the cord may be found. Treatment is directed at the retroviral infection.

### Spinal Cord Infarction

Spinal cord infarction is another diagnosis of exclusion. Aortic dissection, surgery, and global ischemia are the more common causes, although this disorder may occur as a complication of systemic lupus erythematosus, vasculitis, or may be cryptogenic. An anterior spinal cord syndrome is the most common clinical picture. Recovery is variable and depends on the etiology.

### Extrinsic Cord Lesions

#### Spinal Epidural Hematoma

**Principles.** Spinal epidural hematoma is a relatively rare condition. The etiology may be traumatic after lumbar puncture, epidural anesthesia, or spinal surgery. Spinal epidural hematoma is more likely to occur in anticoagulated or thrombocytopenic patients or in patients with liver disease or alcoholism. Spontaneous bleeding is rare but may arise from spinal or dural arteriovenous malformation or vertebral hemangioma. Approximately one fourth to one third of all cases are associated with anticoagulation therapy, including low-molecular-weight heparin.

**Clinical Features.** The patient with a spinal epidural hematoma usually presents with sudden, severe, constant back pain with a radicular component. Onset may follow a straining episode. The pain is often worsened by percussion over the spine and maneuvers that increase intraspinal pressure, such as coughing, sneezing, or straining. The pain often causes the patient to seek care before the development of neurologic signs, possibly leading to delays in diagnosis. Neurologic deficits follow and may progress during hours to days.

The patient usually is in significant distress from the pain. Motor and sensory findings depend on the level and size of the hematoma and can include weakness, paresis, loss of bowel or bladder function, and virtually any sensory deficit.

**Differential Diagnosis.** Considerations in the differential diagnosis include abscess, epidural neoplasm, acute disk herniation, and spinal subarachnoid hemorrhage.

**Diagnostic Testing.** MRI (with and without intravenous [IV] contrast) is the diagnostic study of choice.

**Management.** In patients with a spinal epidural hematoma, recovery without surgery is rare. Neurosurgical consultation for emergent decompressive laminectomy is indicated as soon as the diagnosis is considered. Functional recovery is related primarily to the length of time the symptoms are present. Recovery after 72
hours of symptoms is rare but has been reported even without surgery.

Spinal Epidural Abscess

**Principles.** SEA is an infectious process usually confined to the adipose tissue of the dorsal epidural space, where there is a rich venous plexus. Major risk factors include diabetes, injection drug abuse, chronic renal failure, alcoholism, and immunosuppression, although the disease can be seen in patients who have none of these conditions.** Recent infection is also a described risk factor. Whereas the disease may be manifested in subacute and chronic forms, the acute presentation is seen most frequently in the ED.

Thoracic and lumbar sites of infection predominate, with vertebral epidural abscess being much less common. Infection typically extends over four or five spinal vertebral segments. The dura mater limits the spread of an epidural infection, making subdural or intraspinal spread uncommon. Hematogenous spread of infection to the epidural space is the most common source (seen in 26% to 50% of cases), either to the epidural space or to the vertebra with extension to the epidural space.

Skin and soft tissue infections are the most frequently identified source, reported in 15% of cases; *Staphylococcus aureus* is the most prevalent organism, being cultured in more than 50% of cases. Other frequently identified pathogens include aerobic and anaerobic streptococci, *Escherichia coli*, and *Pseudomonas aeruginosa*. Multiple organisms are identified in approximately 10% of cases; no organism is identified in 40%. With SEA, damage to the spinal cord can be caused by direct compression on neural or vascular structures, by thrombosis and thrombophlebitis of nearby veins, or by a focal vasculitis mediated by bacterial and inflammatory substances.

**Clinical Features.** The classic clinical presentation of SEA begins with a backache that progresses to localized back pain often associated with tenderness to percussion. The duration of symptoms is typically a few days but may extend for weeks. Fever, sweats, and rigors are reported in 30% to 75% of patients. The classic triad of back pain, fever, and progressive neurologic deficits is present in only a few patients, however, and delayed clinical diagnosis is common. Radicular symptoms may not be present initially but usually develop as the disease progresses.

Without treatment, myelopathic signs will develop, usually beginning with bowel and bladder disturbance. Weakness ensues, followed by paraplegia or quadriplegia. Approximately 10% of patients with SEA present with delirium.

**Differential Diagnosis.** Any compressive spinal lesion can mimic SEA.

**Diagnostic Testing.** MRI with IV contrast is the imaging modality of choice and should be performed emergently if the diagnosis of SEA is entertained. Spinal CT is not recommended due to bone artifact.

A complete blood count may support the diagnosis, although it is neither a sensitive nor specific test; a leukocytosis is commonly present with a typical white blood cell count of 13,000 to 16,000/µL. The erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) tests, although not specific for epidural abscess, are virtually always elevated with this condition and have been used as screening tests for SEA in an “at-risk” population. In one study, an elevated ESR or CRP had a sensitivity of 100% and a specificity of 67% for identifying an SEA. External validation is needed, but this may be a future promising risk-stratification method.

Lumbar puncture is relatively contraindicated with known epidural abscess. If performed, CSF findings are consistent with a parameningeal infection, showing elevation of protein and some increase in inflammatory cells.

**Management.** Urgent surgical consultation for decompression is usually required. Antibiotics effective against the most common pathogens (particularly *S. aureus*) should be started empirically. One possible regimen that covers gram-positive and gram-negative organisms consists of a third-generation cephalosporin (ceftriaxone 2000 mg every 24 hours) plus vancomycin (15 to 20 mg/kg IV every 8 to 12 hours), both given intravenously, plus rifampin (10 mg/kg by mouth or IV once a day).

Outcome is related to the speed of diagnosis before the development of myelopathic signs. The disease is fatal in up to 25% of cases, and patients with neurologic deficit rarely improve if surgical intervention is delayed more than 12 to 36 hours after onset of paralysis. Patients operated on before development of neurologic symptoms generally have good outcomes.

Diskitis

**Principles.** Diskitis is an uncommon primary infection of the nucleus pulposus, with secondary involvement of the cartilaginous endplate and vertebral body. It may occur after surgical procedures or spontaneously, the latter being more common in pediatric patients. An increased incidence of diskitis has been noted in immunocompromised patients and in patients with systemic infections. The lumbar spine is the most common site of disease. Both a chronic disease and a more common acute course have been described.

**Clinical Features.** Patients present with moderate to severe pain, localized to the level of involvement and exacerbated by almost any movement of the spine. Elevated temperature is noted in more than 90% of patients. Radicular symptoms are present in 50% to 90% of cases. However, neurologic deficits are the exception with diskitis. Often there is a latent period (2 to 8 weeks) before the onset of back pain and the development of other clinical symptoms or abnormalities on the physical examination. *S. aureus* is the most common pathogen, but gram-negative, fungal, and tuberculous infections all have been recognized.

**Differential Diagnosis.** Considerations in the differential diagnosis include vertebral osteomyelitis, SEA, neoplasm, and hematoma.

**Diagnostic Testing.** Plain radiographs usually are not helpful for early diagnosis of diskitis, but destruction of the disk space is highly suggestive if present. The radiographic findings become abnormal after 2 to 4 weeks of disease. In addition to disk space narrowing, plain films may show irregular destruction of the vertebral body endplates.

MRI with IV contrast is the radiographic study of choice, because it not only diagnoses diskitis but also rules out paravertebral or epidural abscess. Laboratory studies often show an elevated ESR, but the white blood cell count usually is normal.

**Management.** With timely diagnosis and treatment, outcome generally is good, and medical treatment with IV antibiotics that cover staphylococcus and streptococcus in accordance with local resistance patterns is usually curative. We recommend a combination of IV vancomycin (10 to 15 mg/kg) plus IV ceftriaxone (2 gm). If the infectious agent is known or suspected to be pseudomonas, then cefepime (2 gm) could be substituted for ceftriaxone. In patients with a severe penicillin allergy or contraindication to a cephalosporin, meropenem (2 gm) or aztreonam (2 gm) may be substituted for ceftriaxone. Finally, in patients...
with a vancomycin allergy or high resistance, linezolid (600 mg) is recommended. Surgery is generally not necessary.

Neoplasm

Principles. Spinal cord tumors are classified according to their relationship to the dura and spinal cord (extradural, intradural extramedullary, and intradural intramedullary). Spinal cord tumors produce neurologic symptoms by compression, invasion, or destruction of myelinated tracts. The resulting neurologic symptoms are directly related to the growth rate and the location of the tumor. Spinal cord tumors account for 4% to 10% of CNS tumors but for only 1% of all cancers. Most tumors affecting the spinal cord are metastatic. Approximately 10% of patients with known cancer are diagnosed with a spinal metastasis at some point in the course of their disease, and 5% to 10% of patients ultimately diagnosed with cancer first present with a spinal metastasis. Lung cancer, breast cancer, and lymphoma represent more than 50% of the primary malignant neoplasms that subsequently develop spinal metastasis, spreading by both the hematogenous route and direct extension. Most metastases occur in the thoracic spine, and nearly 20% of patients with tumor spread to the spine will have disease at multiple levels.

Clinical Features. In 95% of patients with spinal neoplasm, the initial complaint is pain, either in the back at the level of the tumor or in a radicular distribution. Pain often is characterized as dull, constant, and aching and commonly is said to worsen with recumbency (in contrast with the pain of herniated disk). Night-time pain that is severe is characteristic of spinal neoplasm. Any action that increases intraspinal pressure (Valsalva maneuver, sneeze, cough) may be associated with increased pain. Neurologic deficits vary by the location of the lesion. Besides a thorough neurologic examination, a search for possible primary sites should be done on the physical examination.

Differential Diagnosis. Considerations in the differential diagnosis include any of the compressive lesions (eg, hematoma, infection). Tumor can also mimic intrinsic spinal cord lesions, such as transverse myelopathy and cord infarction.

Diagnostic Testing. Plain radiographs are usually the initial imaging modality in patients with new back pain and no known diagnosis of cancer. The sensitivity and specificity of plain radiographs in detecting abnormalities consistent with malignancy are 60% and 95%, respectively. In the presence of normal radiographs, a normal ESR is diagnostically helpful, in that cancer is very unlikely in a patients with an ESR <20 mm and no risk factors for cancer. Patients with neurologic abnormalities, a history of cancer, and suspicious findings on plain films or elevated ESR are candidates for emergent MRI with IV contrast; CT myelography is an option if MRI is unavailable or the patient has an implantable device precluding MRI.

Management. Acute compressive myelopathy from neoplasm constitutes an oncologic emergency. Immediate treatment is required to preserve function and to prevent deterioration. With onset of paraplegia and incontinence, less than 5% of patients regain ambulatory status. Of patients who are ambulatory at the time of diagnosis, 60% remain ambulatory. High-dose steroids (30 to 100 mg prednisone or equivalent per day), radiotherapy, and surgery all may be necessary acute interventions.

KEY CONCEPTS

- When faced with neurologic dysfunction, the clinician needs to narrow probable location down to brain, cord, or motor end-plate by history and physical examination.
- Complete cord syndromes are characterized by total loss of voluntary motor, sensory, and autonomic innervation distal to the level of cord injury. Partial cord injuries are characterized by sparing of some of these modalities.
- The bulbocavernous reflex is cord-mediated. Return of this reflex following a spinal injury marks the termination of spinal shock.
- Central cord syndrome is frequently the result of hyperextension injuries in the setting of a narrowed cervical canal producing a syndrome of upper extremity > lower extremity effect marked by weakness > sensory deficits.
- Anterior cord syndrome is marked by symmetrical motor loss but intact proprioception and vibration sense.
- In patients with sudden severe back pain, consider spinal subarachnoid hemorrhage or spinal epidural abscess (SEA).
- Myelitis is an inflammation of the spinal cord often caused by a viral infection; steroids have no proven benefit. MRI with contrast enhancement is the diagnostic modality of choice.
- Cauda equina syndrome can be difficult to differentiate from conus lesions because both can result in overflow bladder/fecal incontinence, leg weakness, and sensory loss in the perineum. Conus lesions are more typically bilateral, whereas cauda equina syndrome is unilateral. Upper motor neuron findings are expected with conus lesions but not cauda equina syndrome.
- The diagnostic imaging of choice in the majority of suspected spinal disorders is a MRI with contrast.
- A syrinx is a cavitary lesion in the spinal cord that presents with a sensory disassociation predominately in the upper extremities. With progression, it can lead to upper extremity weakness/wasting. Exacerbation with cough or Valsalva is typical.
- With compressive lesions of the spinal cord, duration of neurologic dysfunction is directly related to ultimate neurologic outcome. The diagnosis should be made expeditiously and definitive therapy begun as soon as possible.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
Canal produces a central cord impingement with an upper overgrowth) or younger individuals with congenitally narrowed narrowing (osteophytes, ligamentum flavum hypertrophy, facet Central cord syndrome is a typically post-traumatic followed by increased muscle tone and hyperreflexia. Squeezing of the glans penis or tugging on the Foley catheter. The Answer: B.

96.2. Which of the following physical findings is a marker for spinal shock? A. Babinski's response present
B. Bulbocavernous reflex absent
C. Lower extremity hyperreflexia present
D. Perineal sensation present
E. Priapism present
Answer: B. The bulbocavernous reflex is a cord-mediated reflex signified by reflex contraction of the anal sphincter in response to squeezing of the glans penis or tugging on the Foley catheter. The termination of spinal shock is heralded by return of this reflex followed by increased muscle tone and hyperreflexia.

96.3. A 49-year-old man presents after a moderate-speed motor vehicle collision. He was an unrestrained driver who was rear-ended at a stop light. He suffered no head impact but reported a whiplash mechanism and complains of neck pain and a mild burning sensation in both palms. Vital signs and physical examination are unremarkable except for posterior cervical paraspinous muscle tenderness and modest allodynia of both palms and fingertips in a nondermatomal distribution. What is the expected finding on magnetic resonance imaging (MRI)?
A. Anterior spinal cord ischemia
B. C5–6 traumatic spondylolisthesis
C. Cervical canal stenosis
D. Normal MRI
E. Unilateral C5–6 disk protrusion
Answer: C. Central cord syndrome is a typically post-traumatic event in either elderly individuals with degenerative cervical canal narrowing (osteophytes, ligamentum flavum hypertrophy, facet overgrowth) or younger individuals with congenitally narrowed canals. A hyperextension mechanism in the setting of a narrow canal produces a central cord impingement with an upper > lower extremity motor > sensory deficit pattern. Bladder dysfunction is variable. Early MRI may show no actual cord changes and only the canal narrowing. Upper extremity dysesthesia may be the only symptom.

96.4. A 73-year-old man is brought to the ED by family members for weakness. His only past history is peripheral vascular disease. He is found to be in septic shock and resuscitated with fluid, antibiotics, blood, and vasopressors. He ultimately requires both dopamine and norepinephrine for maintenance of a mean arterial pressure greater than 60 mm Hg. Approximately 5 hours after arrival, he develops bilateral lower extremity weakness. He has no prior history of back pain or neurologic problems. Which of the following is likely? A. A similar neurologic syndrome after a cervical hyperflexion injury
B. Finding of a mass lesion on MRI
C. Finding of an epidural hematoma
D. Preservation of lower extremity temperature sensation
E. Progressive return of function after 24 hours
Answer: A. Anterior cord syndrome is typically characterized by symmetrical loss of motor function and pain and temperature sensation (both tracts being located in the anterior portion of the cord). Proprioception and vibration sense are usually maintained. Although it may occur after a cervical flexion injury, it is most likely seen after periods of hypotension or instability, such as shock, infection, and myocardial infarction. Most improvement occurs in the first 24 hours.

96.5. What feature most likely distinguishes a conus medullaris from a cauda equina lesion? A. Back pain
B. Bilateral symptoms
C. Distal motor weakness
D. Sacral anesthesia
E. Urinary incontinence
Answer: B. Isolated conus lesions are rare, but because of the small size, they frequently result in bilateral symptoms. Cauda equina syndrome more frequently results in unilateral findings. An additional distinguishing feature may be the presence of upper motor neuron findings in conus medullaris syndrome. Both syndromes may cause overflow bladder incontinence, fecal incontinence, leg weakness, and sensory loss in the perineum.

96.6. A 27-year-old woman presents with complaints of back pain and difficulty walking. Her symptoms have been progressive for 2 days. She has no significant past medical history. Her only other symptom was a bout of influenza approximately 3 weeks prior. Physical examination is remarkable for lower extremity hyperreflexia, moderate symmetrical lower extremity weakness, moderate increased tone, a T10 level of sensory loss, and a postvoid residual urine volume of 350 mL. What should be the next intervention? A. Antibiotics
B. Complete blood count, erythrocyte sedimentation rate (ESR), and antinuclear antibody levels
C. MRI scan

REFERENCES
D. Neurology consultation
E. Steroids

Answer: C. Transverse myelitis is postinfectious in 30% of cases and also idiopathic in 30%. Other causes are autoimmune disorders and infections. Symptoms are typically rapid in onset and progress during 1 or 2 days. Back pain may accompany it. Emergent MRI is indicated to rule out other causes. There is no proven efficacious treatment, although steroids have been used. There is an association with multiple sclerosis (MS). Prognosis for recovery is only fair.

96.7. Which of the following characteristics is a feature of syringomyelia?
   A. Absence of neck pain
   B. Exacerbation with cough or Valsalva maneuver
   C. Loss of vibrating sensation in the arms
   D. Normal cervical MRI
   E. Normal lower extremity examination

Answer: B. Syringomyelia typically presents with headache, neck pain, and variable upper extremity dissociative anesthesia: symmetrical loss of pain and temperature sensation with preserved posterior column function. With progression, upper extremity weakness or wasting and lower extremity upper motor neuron changes are expected. Exacerbation with cough and the Valsalva maneuver is typical. There is a 90% association with type I Arnold-Chiari malformation (cerebellar tonsils and medulla projecting into the spinal canal—often the cause of the typical occipital headaches). MRI is diagnostic.
Peripheral Nerve Disorders

David C. Snow | E. Bradshaw Bunney

OVERVIEW

Principles

The nervous system is divided into central nervous system (CNS) and peripheral nervous system (PNS) components. The PNS is subdivided into 12 cranial and 31 spinal nerves. Disorders of the cranial nerves are discussed in Chapter 95. Because diseases of the neuromuscular junction and the myopathies are located distal to the neuron itself, they are also considered separately in Chapter 98. Radiculopathies, which are disorders of the roots of the PNS, are so commonly associated with musculoskeletal neck and back pain that they are mentioned only briefly here and are discussed in detail in Chapter 47.

Current estimates suggest that about 2.4% of the population suffers from peripheral neuropathy, rising to 8% for those over 50 years of age. Diabetes mellitus is a leading contributor.

The simplest approach to diseases of the PNS parallels the CNS model of separating focal from nonfocal disease. In the PNS, the first broad category is the focal group, which can be divided into those with evidence of single versus multiple lesions of peripheral nerves, known respectively as simple mononeuropathies and multiple mononeuropathies (or mononeuropathy multiplex). The second broad category, which constitutes the nonfocal group of peripheral neuropathies, contains the polyneuropathies. These tend to produce bilaterally symmetrical symptoms and signs, reflecting the widespread nature of the underlying pathologic processes.

The evaluation of PNS disease involves a goal-directed history and physical examination targeted at answering the following three questions, each of which corresponds to a stratum of the algorithm presented in Figure 97.1:

1. Are the sensorimotor signs and symptoms symmetrical or asymmetrical?
2. Are the sensorimotor signs and symptoms distal or both proximal and distal?
3. Is the modality involved exclusively motor, sensory, or mixed sensorimotor?

By systematically combining responses to these questions, seven discrete categories of peripheral neuropathy are identified, each of which contains a finite set of possible diagnoses. Because pure motor or sensory findings tend to occur mainly in an asymmetrical, distal distribution, this is the only category in Figure 97.1 subdivided into pure motor and pure sensory abnormalities.

The spinal component of the PNS is shown schematically in Figure 97.2. The anterior and posterior nerve roots exit the spinal cord at each segmental level. Just distal to the dorsal root ganglion they converge to form a mixed (motor and sensory) spinal nerve, of which there are 31 pairs: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. The spinal nerves immediately bifurcate into anterior (ventral) and posterior (dorsal) rami. The posterior ramus travels to the back. The anterior ramus innervates the anterolateral portion of the body and supplies all peripheral nerves for the upper and lower extremities through the brachial and lumbosacral plexus, respectively. Interweaving of fibers occurs within a plexus, producing a mixed sensorimotor innervation of peripheral nerves exiting the plexus.

In addition to the motor and sensory modalities of the PNS, the autonomic nervous system has a peripheral component. Anatomically and functionally, the autonomic nervous system is divided into two parts: (1) a sympathetic (thoracolumbar) component and (2) a parasympathetic (craniosacral) component. Autonomic dysfunction may cause systemic abnormalities, such as orthostasis, or local problems, such as atrophic, dry skin.

The PNS has three basic responses to pathologic stimuli (see Fig. 97.2): (1) the myelinopathies, in which the primary site of involvement is limited to the myelin sheath surrounding the axon; (2) the axonopathies, in which the primary site of involvement is the axon, with or without secondary demyelination; and (3) the neuronopathies, in which the cell body of the neuron itself is the primary site of involvement, ultimately affecting the entire peripheral nerve. Although overlap occurs, each of these prototypes has a distinctive clinical presentation, electrophysiologic profile, and microscopic appearance.

Differential Diagnosis

The differential diagnosis for any patient presenting with sensory, motor, or sensorimotor complaints, particularly if they are localized to the extremities, should include a peripheral neuropathy. Within this group, patients with focal weakness are most concerning, because they are at greatest risk for respiratory compromise. Box 97.1 lists the causes of acute, emergent weakness that may affect respiration.

As soon as the emergent causes of weakness have been excluded, the individuals with focal weakness should be assessed next to exclude CNS disease (eg, stroke; Chapter 91), after which the systematic evaluation of peripheral neuropathy is performed with the distinguishing features of each of the seven peripheral neuropathic patterns described by distribution and modality and represented by a disease prototype (see Fig. 97.1; Table 97.1).

Diagnostic Testing

Testing in the evaluation of the patient with a suspected peripheral neuropathy is presented in Box 97.2. Electrophysiologic testing (nerve conduction studies [NCSs] and needle electromyography [EMG]) detects underlying pathologic abnormalities. Because neither test is readily available in the acute care setting, they are discussed only briefly here. Information gathered from these tests can be used to obtain objective information regarding the anatomic distribution of involvement (symmetrical versus asymmetrical and distal versus proximal and distal) and the modalities involved (sensory, motor, or mixed).

NCSs and EMG can also identify the level of the neuraxis affected by the disease process (ie, root, plexus, or nerve); if the nerve is affected, electrophysiologic testing can help determine whether the lesion is mononeuropathic (either an isolated mononeuropathy or mononeuropathy multiplex) or polyneuropathic.
SPECIFIC TYPES OF NEUROPATHIES

**Type 1: Demyelinating Polyneuropathy (Guillain-Barré Syndrome)**

**Principles**

The pattern of symmetrical weakness, usually worse distally, accompanied by variable sensory findings is characteristic of acute Guillain-Barré syndrome (GBS). It is a heterogeneous and unpredictable disorder, characterized by areflexic paralysis with albuminocytologic dissociation, with marked variation in latency between antecedent infection and symptom onset. Up to 20% of patients remain disabled from this disease process, and about 5% will die despite therapy.

Finally, EMG and NCSs can distinguish axonal from myelin disease, further narrowing the differential diagnosis. Prognosis is determined by the nature of pathologic involvement of the PNS. Primary demyelination spares the axon and thus carries the best prognosis. The prognosis is worse in axonopathies because reestablishment of nerve function is dependent on the much slower process of axonal regeneration. Neuronopathies, which begin with primary destruction of the nerve cell body, produce pure motor or pure sensory syndromes. Eventually the entire nerve is affected, resulting in the worst prognosis of the three.

Expensive batteries of tests purporting to measure a wide variety of antibodies to components of peripheral neuropathies are commercially available but have not been shown to be useful as screening tests.
**BOX 97.1**

**Causes of Acute, Emergent Weakness and Possible Respiratory Compromise**

**Note:** Although several of the disorders listed are myopathies (see Chapter 1098), rather than peripheral neuropathies, they are lumped together here because it is important to identify patients at risk for respiratory failure early in the course of evaluation.

Autoimmune
- Demyelinating
  - Guillain-Barré syndrome (GBS)
  - Chronic inflammatory demyelinating polyneuropathy
- Myasthenia gravis

Toxic
- Botulism
- Buckthorn
- Seafood
  - Paralytic shellfish toxin
  - Tetrodotoxin (puffer fish, newts)
- Tick paralysis
- Metals
- Arsenic
- Thallium

Metabolic
- Dyskalemic syndromes
  - Acquired (especially with thyrotoxicosis)
  - Familial
- Hypophosphatemia
- Hypermagnesemia
- Porphyria
- Infectious
- Poliomyelitis
- Diphtheria

**BOX 97.2**

**Ancillary Diagnostic Testing in Suspected Peripheral Neuropathy**

**OBTAINED IN MOST PATIENTS**
- Complete blood count
- Erythrocyte sedimentation rate
- Glucose
- Creatine kinase
- Creatinine

**OBTAINED IN SOME PATIENTS BASED ON HISTORY**
- Human chorionic gonadotropin
- Magnesium
- Phosphate
- Vitamin B₁₂
- Hemoglobin A₁c
- Serum protein electrophoresis with immune fixation electrophoresis
- Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin screen with fluorescent treponemal antibody absorption test, as appropriate
- Thyroid function
- Human immunodeficiency virus (HIV) titer

ALS, Amyotrophic lateral sclerosis; CTS, carpal tunnel syndrome; DSPN, distal symmetrical polyneuropathy; GBS, Guillain-Barré syndrome.
Demyelinating Polyneuropathies

Guillain-Barré syndrome (GBS)
- Acute inflammatory demyelinating polyradiculoneuropathy
- Acute motor axonal neuropathy
- Acute motor and sensory axonal neuropathy
- Miller Fisher syndrome
- Chronic inflammatory demyelinating polyradiculoneuropathy
- Malignant disease
- Human immunodeficiency virus (HIV) infection
- Hepatitis B
- Buckthorn
- Diphtheria

The most common form of GBS is an acute inflammatory demyelinating polyneuropathy, representing 90% of the cases seen in the United States. Less common variants are acute motor axonal neuropathy, acute motor and sensory axonal neuropathy, and the Miller Fisher syndrome. Acute motor axonal neuropathy, which accounts for most of the remaining cases seen in the United States, afflicts those of Asian descent more often. Miller Fisher syndrome is a rare form of GBS characterized by the triad of ophthalmoplegia, ataxia, and areflexia (Box 97.3).

The most common infectious organisms associated with GBS is Campylobacter jejuni, with 30% noted in one study. Cytomegalovirus, Epstein-Barr virus, and Mycoplasma pneumonia are also associated with subsequent development of GBS.

Clinical Features

The majority of patients seek treatment days to weeks after resolution of an upper respiratory or gastrointestinal illness, presenting with progressive, symmetrical distal (and usually to a lesser extent proximal) weakness. Symptoms can progress over a period of up to 28 days, casting doubt on the diagnosis in a patient with rapidly developing symptoms. Signs and symptoms are usually worse in the lower extremities and are associated with diminution or loss of deep tendon reflexes (DTRs), variable sensory findings, and sparing of the anal sphincter. The presence of distal paresthesias increases the likelihood of GBS as the diagnosis.

The GBS disability score, which combines age, presence or absence of diarrhea, and a score of the patient’s ability to ambulate independently at 2 weeks, has been shown to be predictive of prognosis at 6 months, particularly related to independent activity. Tongue weakness has been found to be associated with the development of respiratory compromise and the need for mechanical ventilation in patients with GBS. Compared with adults, children who have GBS have neuropathic pain more often (80%) and require mechanical ventilation less often (13%).

Diagnostic Testing

GBS is typically diagnosed on clinical findings, but additional testing is available when the diagnosis is uncertain. EMG can be used in such instances. Signs of demyelination including nerve conduction slowing with prolonged distal motor latency are the most frequent demyelinating parameter.

In addition to electrophysiologic testing, cerebrospinal fluid (CSF) analysis, and respiratory function testing may aid in the diagnosis of GBS. CSF analysis is useful when it demonstrates the characteristic picture of markedly elevated protein with only a mild pleocytosis (albuminocytologic dissociation). In the clinical setting of suspected GBS, this finding is highly specific. Early in the disease, however, patients may have normal CSF values. One study noted only 50% of patients with this finding in the first week of symptoms, rising to 75% in the third week. Consequently, a normal CSF value cannot be used to exclude GBS.

Individuals with suspected GBS should have their respiratory function tested. A decrease in forced vital capacity (FVC) correlates with the need for intubation in patients with GBS. A FVC of less than 20 mL/kg is associated with pending respiratory failure and the need for intubation, whereas patients with an FVC of more than 40 mL/kg do not usually require intubation. Likewise, patients with a negative inspiratory force of less than 30 cm H2O are more likely to require mechanical ventilation. Other tests, such as the forced expiratory volume in 1 second (FEV1) and peak flow rate (PFR), can also be used to assess respiratory function. Patients unable to perform these tests and those with less than 100% of predicted values should have an arterial blood gas sample obtained.

Management

In practice, patients with symmetrical weakness of relatively acute onset, decreased or absent DTRs, and variable degrees of sensory loss are managed as if they have GBS or one of its variants. These patients have a greater risk for respiratory compromise, which develops in 20% to 30% of patients. Conversely, patients with predominantly sensory signs and symptoms are less likely to develop acute respiratory distress and have a more favorable prognosis.

About half of patients with GBS have autonomic dysfunction, experience a peak of disease severity within a week of onset, have some form of cranial nerve involvement (usually VII), and suffer long-term sequelae of their illness.

The definitive treatments for GBS are plasma exchange or intravenous immune globulin (IVIG). Both of these treatments are supported by well-designed studies, although there are no studies comparing IVIG to placebo. Combination or sequential therapy confers no therapeutic advantage over either intervention alone. Plasma exchange is cumbersome and not available at many hospitals. IVIG is more readily available and is usually administered in a dose of 400 mg/kg per day for 5 days. However, IVIG is expensive, costing roughly double a standard course of plasma exchange.

Corticosteroids are not recommended; oral steroids have been shown to delay recovery, and intravenous steroids alone have been shown to impart no benefit. The combination of intravenous steroids and IVIG appears to hasten recovery but does not effect on long-term outcome and is not currently recommended.

Disposition

Patients with probable GBS should receive neurologic consultation and admission for airway monitoring and treatment with either plasma exchange or IVIG. Evidence of alveolar hypoventilation (elevated carbon dioxide [PaCO2]) in a patient with an unsecured airway requires an intensive care level of monitoring and considered for early, prophylactic intubation.

Type 2: Distal Symmetrical Polyneuropathy

Principles

Distal symmetrical polyneuropathy (DSPN) is the most common type of peripheral neuropathy. Diabetes, alcoholism, human immunodeficiency virus (HIV) disease, and toxic metabolic causes are the most frequent etiologies (Box 97.4). DSPN in diabetics, termed diabetic polyneuropathy, is the most common chronic complication of diabetes mellitus.

Although the association between alcoholism and peripheral neuropathy has been well established for centuries, demonstration
of a direct neurotoxic effect of alcohol remains elusive. The preponderance of evidence from both observational studies in humans and experimental data from animal models suggests that the association between alcohol and peripheral neuropathy may be confounded by nutritional status (ie, deficiency states might be the true underlying cause of alcoholic peripheral neuropathy).

With the widespread use of highly active and effective antiretroviral treatment, peripheral neuropathies have become the most common neurologic complication of HIV infection. The typical HIV neuropathy is a DSPN, estimated to affect up to 35% of the HIV population, with a currently unknown pathogenesis.

Clinical Findings

Most polyneuropathies are characterized by a pattern of distal, symmetrical sensorimotor findings, worse in the lower than in the upper extremities, with a stocking-glove distribution of sensory abnormalities that gradually diminishes as one moves proximally. Motor weakness and loss of DTRs, which lag behind the sensory features, follow a similar pattern of progression from distal to proximal. The diffuse, distal, symmetrical nature of this pattern is most consistent with a toxic-metabolic disease process that causes a length-dependent axonopathy.

Initial symptoms usually consist of “positive” sensory complaints (eg, dysesthesias, such as tingling and burning) beginning on the plantar surfaces of both feet. At the early stages of a typical DSPN, there may be some asymmetry. At this juncture, it may be impossible to distinguish a focal neuropathic process such as a mononeuropathy from a polyneuropathy, although in this location, prior probability strongly favors a polyneuropathy. As the process advances, the plantar surfaces of both feet become dysesthetic before the dorsum of either foot is involved.

Weakness of dorsiflexion of the big toe is usually the first motor sign, followed by weakness of foot dorsiflexion, footdrop, loss of the Achilles reflex, and later a “steppage gait,” in which footdrop causes the toes to point downward and scrape the ground while walking, requiring the patient to lift the leg higher than normal when walking.

Sensory loss continues to move proximally, and before it reaches the knees, the fingertips are usually involved. DTRs are progressively lost, as is proprioception. If loss of proprioception becomes severe, patients may develop sensory ataxia. As the neuropathy continues to progress, sensory abnormalities ultimately involve all modalities and extend to a diamond-shaped periumbilical area. Far-advanced disease may affect sensation over the skull vertex and facial midline structures. Atrophy and areflexia may occur as weakness worsens. Severely impaired patients may be unable to ambulate or to grasp objects. These symptoms have a significant impact on the patient’s quality of life, affecting not only physical functioning but also sleep and emotional and social functioning. Many of these patients display signs of depression or anxiety. Polyneuropathies can be difficult to diagnose and are best approached by the performance of electrodiagnostic studies for patients with a constellation of symptoms and signs suggesting a particular neuropathy.

Diabetic foot ulcers are a common complication of diabetes, ranging from 2% to 10% of the population. Unperceived trauma is the leading cause, likely from the associated polyneuropathy.8

The clinical picture of alcoholic neuropathy is similar to that of diabetic DSPN. However, in alcoholism, severe myopathy and cerebellar degeneration often complicate the clinical picture. Autonomic skin changes with atrophy and hair loss accompany the sensorimotor abnormalities. Often, other systemic effects of alcoholism are so severe that the patient may not notice the neuropathic symptoms.
Differential Diagnosis

Box 97.4 lists the differential diagnoses of DSPN. On the basis of results from a case-control study, the statins have been added to the list of drugs that are implicated.

Diagnostic Testing

Electrodiagnostic studies are commonly employed in the evaluation for this entity. This includes both NCSs and needle electromyography. Screening laboratory tests should be considered for all patients who present with this condition. The tests that provide the highest yield include blood glucose, serum B12, and serum protein immunofixation electrophoresis.

Management

Diabetic DSPN, the first step in the treatment, is intensive diabetes therapy aimed at near normoglycemia. If discomfort is severe, the etiology of the neuropathy seems likely to be diabetic, and if referral is delayed, it may be necessary to provide the patient with some symptomatic relief. Because treatment of neuropathic pain has traditionally been linked to etiology rather than to an underlying mechanism, the choice of pharmacologic agents is empirical, with substantial practice variation in the United States and worldwide. Nonsteroidal antiinflammatory drugs (NSAIDs) should not be considered first-line treatment, because they have little proven efficacy and a high potential for renal impairment. High level evidence supports the use of tricyclic antidepressants, anticonvulsants, and the serotonin and norepinephrine reuptake inhibitor nuloxetine. Imipramine or amitriptyline may be started at a daily dose of 25 mg at bedtime (10 mg in elders) and titrated slowly up to a dose of 150 mg. Carbamazepine at a dose of 200 to 400 mg every 8 hours and gabapentin at a dose of 900 to 3600 mg per day are also effective treatments. Tramadol, a mixed opioid with low potential for dependency, has been shown in two studies to have efficacy and a high potential for renal impairment. Most effective treatments for neuropathic pain have limited its use. Topical lidocaine patches, 5%, are another treatment option, showing similar efficacy to pregabalin.

In addition to pain management as discussed earlier, all patients with suspected alcoholic DSPN should receive dietary supplements and referral for outpatient management.

Lamotrigine has been shown to be effective in the treatment of HIV-associated painful neuropathies, especially for those patients on highly active antiretroviral therapy (HAART). However, there are no comparative studies to support its use over the other pain medications.

Type 3: Asymmetrical Proximal and Distal Peripheral Neuropathies (Radiculopathies and Plexopathies)

Radiculopathies (see Chapter 47) and plexopathies often result from trauma (Box 97.5). In general, a plexopathy, whether brachial or lumbosacral, is identified by a process of elimination (ie, a pattern of sensorimotor and reflex abnormalities that fit neither a radicular nor an individual peripheral nerve distribution). Although this approach does not exclude a mononeuropathy multiplex on physical examination alone, a careful history should determine whether the patient is at risk for development of a mononeuropathy or plexopathy on the basis of underlying disease.

Most plexopathies are seen in young men after motor vehicle accidents. Most present for evaluation of radicular pain several months after the initial injury. Therapeutic intervention is often delayed to maximize the potential for spontaneous recovery. Several surgical repairs exist, including neurotization and nerve transfer.

Radiation (actinic) plexopathy occurs after a variable period of latency following treatment, which may extend to 20 years or more. Almost all series include women who received radiation treatment for breast cancer. Among neoplastic causes, most originate from the lung or breast. Patients with probable neoplastic brachial plexopathy need imaging studies and may require immediate radiation therapy. Pain control is the focus of management.

Thoracic outlet syndrome (TOS) describes a constellation of symptoms caused by compression of the neurovascular bundle at the thoracic outlet. As our understanding of this condition has improved, treatment has evolved but remains controversial. Manifestations include both neurogenic and vascular (arterial or venous) TOS. It is estimated that over 90% of cases are neurogenic in origin, 3% to 5% are venous, and less than 1% are arterial.

Neurogenic TOS is caused by compression of the brachial plexus, presenting with upper extremity weakness, numbness, paresthesias, and pain in a nonradicular distribution. Symptoms are usually present during normal daily activities and sleep.

### BOX 97.5

**Asymmetrical Proximal and Distal Peripheral Neuropathies**

**BRACHIAL PLEXOPATHY**

Open
- Direct plexus injury (knife or gunshot wound)
- Neurovascular (plexus ischemia)
- Iatrogenic (central line insertion)

Closed
- Traction injuries
- “Stingers”
- Traction neurapraxia
- Partial or complete nerve root avulsion
- Radiation
- Neoplastic
- Idiopathic brachial plexitis
- Thoracic outlet

**LUMBOSACRAL PLEXOPATHIES**

Open

Closed

- Cytomegalovirus polyradiculopathy (HIV infection)

HIV, Human immunodeficiency virus.
CHAPTER 97  Peripheral Nerve Disorders

Radial Mononeuropathy

Principles. The radial nerve arises from the C5 to T1 roots. After exiting the brachial plexus, it passes behind the proximal humerus in the spiral groove and takes a lateral (radial) course down the upper arm (Fig. 97.3). At about the level of the antecubital fossa, it bifurcates into the posterior interosseous (pure motor) and superficial radial (pure sensory) nerves. The radial nerve controls extension of the fingers, thumb, wrist, and elbow (triceps). In contrast to the median and ulnar nerves, the radial nerve provides only extrinsic motor innervation to the hand (ie, it does not supply motor fibers to any muscles that both originate and insert within the hand). In further contrast to the median and ulnar nerves, the radial nerve provides only extrinsic motor innervation to the hand (i.e., it does not supply motor fibers to any muscles that both originate and insert within the hand). In further contrast to the median and ulnar nerves, which supply most of the interosseous muscle, the radial nerve supplies only the triceps. 

Type 4: Isolated Mononeuropathies

The pattern of asymmetrical, sensorimotor, usually distal, peripheral neuropathy is characteristic of a mononeuropathy. Mononeuropathies are of two main types: isolated and multiple. The isolated mononeuropathies are discussed in this section; the multiple mononeuropathies, also termed mononeuropathy multiplex, are discussed in the next section as a type 5 peripheral neuropathy.

Isolated mononeuropathies are usually caused by trauma, either blunt or penetrating (Box 97.6). If the trauma is blunt, the injury may be secondary to compression from an internal or external source. Entrapment neuropathies are a subset of compression neuropathies occurring at anatomic locations where nerves traverse potentially constricting compartments or tunnels. Isolated mononeuropathies may be acute, intermittent, or chronic and continuous. Antecedent peripheral neuropathy may be a risk factor for development of compression neuropathy (so-called double-crush syndrome), particularly in diabetics.

BOX 97.6

Isolated Mononeuropathies

**UPPER EXTREMITY**

Radial nerve
- Axilla
- Humerus
- Elbow (posterior interosseous neuropathy)
- Wrist (superficial cutaneous radial neuropathy)

Ulnar nerve
- Axilla
- Humerus
- Elbow
- Condylar groove
- Cubital tunnel
- Wrist (Guyon’s canal)
  - Hand
    - Superficial terminal ulnar neuropathy
    - Deep terminal ulnar neuropathy: proximal hypothenar; distal hypothenar

Median nerve
- Axilla
- Humerus (musculocutaneous mononeuropathy)
- Forearm
  - Anterior interosseus
  - Pronator syndrome
- Wrist (carpal tunnel)
- Hand (recurrent motor branch)

**LOWER EXTREMITY**

Sciatic nerve
- Iliacus compartment (proximal)
- Saphenous mononeuropathy (distal)
- Lateral femoral cutaneous (meralgia paresthetica)
- Peroneal nerve
  - Common peroneal mononeuropathy (fibular head, popliteal fossa)
  - Deep peroneal mononeuropathy (anterolateral compartment)
- Tibial nerve
  - Popliteal fossa (proximal)
  - Tarsal tunnel (distal)
- Sural nerve
  - Popliteal fossa, calf (proximal)
  - Fifth metatarsal base (distal)
- Plantar nerve
  - Distal to tarsal tunnel
  - Interdigital neuropathies (Morton’s neuroma)
- Obturator mononeuropathy

Fig. 97.3. Radial nerve, major branches, right arm, lateral view. (From Stewart JD: Focal peripheral neuropathies, ed 3, Philadelphia, 2000, Lip- pincott Williams & Wilkins.)
sensation to the hand, the radial nerve makes a contribution only to a cutaneous dorsal area overlying the first dorsal interosseous muscle, sometimes extending part of the way up the dorsa of the thumb, index, and long fingers.

Radial mononeuropathy caused by involvement at the level of the axilla is uncommon. When it occurs, it is usually associated with other upper extremity mononeuropathies or a brachial plexopathy. Although improper use of crutches may cause this syndrome, it usually occurs after an extended period of unconsciousness during which the arm is positioned in such a way that prolonged, deep compression is applied to the axilla. Auxiliary radial mononeuropathy is distinguished from the more common humeral form by the finding of triceps involvement in addition to typical wrist and finger drop. Triceps involvement occurs because the innervation to the triceps is proximal to the point where the nerve is most vulnerable as it winds around the humeral shaft (see Fig. 97.3).

Most radial mononeuropathies are due to so-called Saturday night palsies. The eponym is derived from the association of radial mononeuropathy with improper positioning of the arm during deep, commonly inebriated sleep. Consequently, the radial nerve is trapped for a prolonged period between the humeral shaft and some firm surface, causing an external compression mononeuropathy. “Bridegroom’s palsy” is another eponym for radial mononeuropathy, so named because the radial nerve may be compressed by the bride’s head resting on the bridegroom’s arm during sleep.

Clinical Findings. Because innervation of the wrist and finger extensors occurs distal to this area of the humeral shaft, findings are characterized by wrist and finger drop and mild numbness over the skin of the first dorsal interosseous muscle. Depending on the level, degree, and duration of compression, some fascicles of the nerve may remain functional, resulting in a partial radial mononeuropathy. Thus the superficial radial nerve may remain intact, resulting in no loss of sensation, or loss of wrist and finger extension may be incomplete.

Because the finger drop of radial mononeuropathy places the hand at a mechanical disadvantage, examination of ulnar function by testing of the interossei may produce false-positive findings of weakness. To adjust for this, the examiner should ask the patient to place the palm on a horizontal supporting surface, such as a stretcher. With the fingers extended and no longer “dropped” at the metacarpophalangeal joints, interosseous strength can now be fairly tested. Failure to perform this maneuver may cause misdiagnosis of a simple radial mononeuropathy as a brachial plexopathy in an effort to explain what appears to be radial and partial ulnar nerve involvement.

About 90% of radial nerve palsies occurring during sleep, coma, or anesthesia recover fully, usually within 6 to 8 weeks. Evidence of denervation on EMG studies predicts a slower rate of recovery. Tourniquet injuries to the radial nerve usually recover spontaneously within 2 to 4 months. If axonal degeneration is seen on electrophysiologic testing, recovery may take longer, although virtually all radial mononeuropathies caused by tourniquets eventually resolve.

The radial nerve courses closely to the humerus, so it follows that about 22% of humeral shaft fractures are associated with radial nerve injury, with “wrist drop” the hallmark injury. Spon- taneous resolution has been reported between 60% and 92%, so many authors suggest observation of these injuries is appropriate. In contrast, surgical intervention is needed to free the nerve from entrapment associated with complex fractures.

Diagnostic Testing. There exists no diagnostic test per se for this disease entity outside of the physical examination. EMG testing is employed to aid in predicting recovery times.

Management. While patients are waiting for spontaneous recovery to occur, the hand should be maintained in about 60 degrees of dorsiflexion. Although a simple dorsal plaster or fiberglass splint treats the wristdrop, atrophy and contractures can be minimized and function of the hand can be improved if wide rubber bands anchored to the splint at a point proximal to the wrist are attached to individual fingers to provide passive dorsiflexion.

Ulnar Mononeuropathy

Principles and Clinical Findings. The ulnar nerve includes C7 to T1 roots and passes through the brachial plexus to descend medially, without branching, to the ulnar (medial) condylar groove at the elbow. It then enters the cubital canal, where it gives off branches to the ulnar wrist flexor and the deep flexors of the fourth and fifth digits.

Just proximal to the wrist, two important sensory branches leave the main trunk to supply cutaneous sensation to part of the hand (Fig. 97.4). These are the palmar and dorsal cutaneous branches, which do not pass through Guyon’s canal. The palmar branch supplies sensation to the hypothenar eminence and the dorsal branch innervates the ulnar side of the dorsum of the hand, extending out nearly to the tip of the fifth and ulnar half of the fourth digit.

At the wrist, the nerve enters Guyon’s canal (Fig. 97.5) between the pisiform and hook of the hamate, then bifurcates into the superficial terminal sensory branch and the deep motor branch.

The superficial sensory nerve supplies ulnar sensation to the palmar side of the fifth and half of the fourth digit (see Fig. 97.5). The deep motor nerve supplies the hypothenar muscles, then crosses to the radial side of the palm to innervate the ulnar intrinsic (all interossei and the ulnar lumbricals of the fourth and fifth
digits), terminating in the first dorsal interosseous. The interossei abduct and adduct the fingers and are all innervated by the ulnar nerve. The lumbrical muscles flex the metacarpophalangeal joints and are evenly divided between the ulnar (fourth and fifth) and median (second and third) digits. The ulnar nerve can be thought of as the complement to the median nerve in the hand, because it supplies all of the muscles and all palmar sensation not innervated by the median nerve.

The ulnar nerve may be injured at two locations near the elbow: in the ulnar condylar groove and distally in the cubital canal. Because the condylar groove is shallow, the ulnar nerve runs superficially in this location and is vulnerable to injury, usually from external pressure or from a fracture or dislocation. The ulnar nerve has a propensity to develop a “tardy ulnar palsy,” occurring years after a traumatic event. Many of these delayed ulnar mononeuropathies can be localized to the elbow on electrophysiologic testing.

Some ulnar mononeuropathies occur secondary to compression just proximal to entry into the cubital canal or are entrapped within the canal itself. Transient symptoms may occur during prolonged flexion or with repeated flexion and extension at the elbow.

Although it is difficult to distinguish a condylar from a cubital ulnar mononeuropathy, it is usually possible to localize the problem to the region of the elbow or the wrist. In addition to prior probability heavily favoring the elbow, the presence of sensory abnormalities in an ulnar distribution in the hand and fingers (ie, usually including the fifth digit and “splitting” the fourth digit) strongly suggests that the lesion is at the level of the elbow rather than the wrist. The ulnar cutaneous innervation to the hand branches off from the main trunk proximal to the nerve entering Guyon’s canal (see Figs. 97.4 and 97.5). Thus a lesion at the wrist should not produce sensory abnormalities, whereas one at the elbow would be expected to do so.

Compression of the ulnar nerve within Guyon’s canal is rare. When it does occur, it affects all of the ulnar intrinsics (ie, the two ulnar [fourth and fifth] lumbricals) and all the interossei. However, the ulnar extrinsics (ie, the deep flexors of the fourth and fifth digits) are not affected, nor is the ulnar flexor of the wrist. The only sensory abnormalities are those in the distribution of the superficial terminal sensory branch, sparing other areas of ulnar innervation (see Fig. 97.5).

There are three ulnar mononeuropathies that occur distal to Guyon’s canal in the hand. The two most common involve the deep terminal branch, either proximal or distal to the separation of the hypothenar branches (see Fig. 97.5). If the lesion is proximal, it produces weakness of all the ulnar-innervated muscles of the hand without sensory loss. If it is distal, the hypothenar ulnar intrinsics are spared, but the picture is otherwise similar. Usually, this occurs secondary to a laceration or repeated compression in the hand from use of certain tools, a cane, or the handle of a crutch.

Involvement of the superficial terminal branch (see Fig. 97.5) produces a pure sensory loss of the palmar surface of the fifth digit and ulnar half of the fourth digit caused by direct compression of this branch just distal to Guyon’s canal. The dorsal surface of these two digits should have normal sensation except for the distal tips. This configuration of findings is due to the intact innervation provided by the dorsal and palmar cutaneous branches that enter the hand without passing through Guyon’s canal (see Fig. 97.4).

**Diagnosis.** There is no true diagnostic entity for this disease process outside of the physical examination.

**Management.** Most ulnar mononeuropathies will spontaneously resolve. However, if muscle atrophy, particularly in the hypothenar area, is detected, surgery may be considered. There is no noted difference in outcomes between the two surgical options of simple decompression and decompression with transposition.

### Median Mononeuropathy

**Principles.** The median nerve arises from the C5 to T1 spinal nerve roots and exits the brachial plexus through the lower trunk (Fig. 97.6). Median mononeuropathy is usually diagnosed as carpal tunnel syndrome (CTS), which is the most common of all entrapment neuropathies. CTS is estimated to occur in 3.8% of the United States population, with a prevalence of 9.2% in women and 6% in men. It is defined by the Academy of Orthopedic Surgeons as “a symptomatic compression neuropathy of the median nerve at the level of the wrist.”

**Clinical Findings.** Although the patient may complain of bilateral symptoms, a careful history usually reveals that symptoms in one hand preceded those in the other. A common symptom of CTS is awakening at night and shaking the hand. Symptoms are often worsened by activity. For unclear reasons, the pain may spread as high as the arm or shoulder, although the paresthesias are generally confined to the fingers. Many patients on initial questioning state that their entire hand is involved, although this is not supported by careful sensory examination. Patients frequently note that their hands are clumsy or weak, especially when holding a glass or opening a screw-top container. The skin of the fingers innervated by the median nerve may be drier and rougher to the touch than the corresponding ulnar skin, depending on the duration of entrapment.

When motor involvement occurs in CTS, it is confined to the median intrinsics, which innervate the lumbricals (flexion of the metacarpophalangeal joints) and subserve thumb opposition, abduction, and flexion, known as the LOAF muscles. However, the hallmark of CTS is sensory involvement, with motor abnormalities occurring later. The typical pattern of sensory innervation of the hand by the median, ulnar, and radial nerves shows marked individual variation. The most specific finding for CTS is splitting of the fourth digit (ie, normal sensation of the ring finger on the ulnar palmar side with abnormal sensation on the median [radial]
Diagnostic Testing. Tinel’s sign (percussion of the median nerve at the wrist) and Phalen’s sign (maximal palmar flexion at the wrist) have been classically taught as provocative tests to reproduce the sensory symptoms of CTS if neither sensory nor motor symptoms are evident on initial examination. However, more recent evaluation has shown that Tinel’s and Phalen’s signs do not have adequate sensitivity or specificity to determine which patients should be referred for electrodagnostic studies. Dropping of objects is indicative of severe CTS. The best way to examine patients for sensory findings is to touch the distal palmar tips very lightly, asking the patient whether the sensation feels “abnormal.”

NCS is considered to be the gold standard in the diagnosis of CTS, because it is an objective test that provides information on the physiological health of the median nerve across the carpal tunnel. Magnetic resonance imaging (MRI) allows for good imaging of the soft tissue structures of the carpal tunnel and revealing the cause of the nerve compression. It has a sensitivity of 96% but a specificity of 33% to 38%. Ultrasoundography has been shown to be useful, particularly in patients with symptoms and a normal NCS. The most reliable ultrasonographic measurement is to obtain the cross-sectional area of the median nerve at the level of the pisiform. Thus, if all diagnostic studies in a symptomatic patient have normal findings, or if only the MRI result is abnormal, they should be repeated within a few months if symptoms do not resolve. This recommendation is based on the theory that the CTS will progress over time to the point that an objective indicator, such as the NCS, will become positive.

Management. There are a variety of nonsurgical treatments, with splinting and steroid injections being the most common. Neutral wrist splinting has commonly been used as the initial treatment, but a recent Cochrane review found poor evidence to support this being more effective than no treatment in the short term. Steroid injection has been shown to be a temporizing measure in the treatment of CTS. One recent study using methylprednisolone showed significant symptom relief at 10 weeks and also reduced the rate of surgery at 1 year. Because of the possibility of a disabling “median hand” after inadvertent direct injection of the median nerve, it is recommended that emergency clinicians defer the injection of the carpal tunnel with steroids to the consulting hand surgeon. This physician can obtain NCS and determine splinting, injection, or surgical division of the transverse carpal ligament is indicated. Surgical treatment involves the division of the transverse carpal ligament, which reduces pressure on the median nerve by increasing the space in the carpal tunnel. This carpal tunnel “release” surgery can be performed open or endoscopic with no significant difference in outcomes noted.

Sciatic Mononeuropathy

Principles. The sciatic nerve includes L4 to S3 spinal nerve roots that pass through the lumbosacral plexus and divides into two terminal branches: the common peroneal and tibial nerves. The nerve exits the pelvis through the sciatic notch, passes behind the hip, and remains deep in the thigh until its terminal bifurcation in the proximal popliteal fossa (Fig. 97.7). Lesions of the sciatic nerve occur with posterior hip dislocation or with virtually any form of penetrating or blunt trauma that causes formation of a buttock hematoma. Other causes include deep gluteal injection and prolonged supine immobilization on a firm surface. Because the sciatic nerve innervates the hamstrings and provides all sensorimotor function distal to the knee, a complete sciatic mononeuropathy is a devastating injury.

Clinical Findings. Ambulation is extremely difficult because of inability to flex the knee and a flail foot (ie, neither flexion nor

---

palmar side of the same finger). The most sensitive finding is abnormal sensation of the distal palmar tip of the index finger. If sensory findings are absent in the presence of motor findings consistent with median nerve involvement, it is highly unlikely that the patient has CTS, and an alternative diagnosis should be sought.

CTS appears to be associated with the conditions listed in Box 97.7. Of these, the two most common are diabetes mellitus and pregnancy. CTS associated with systemic illness is commonly bilateral. CTS in pregnancy appears to be common, but the prevalence varies widely literature from 31% to 62%. Most cases of pregnancy related CTS resolve spontaneously, up to 85% in some studies.
extension is possible at the ankle). Fortunately, many sciatic mononeuropathies are incomplete. For unknown reasons, a partial lesion typically involves only the trunk of the sciatic nerve, which subsequently becomes the common peroneal nerve, sometimes making the two difficult to distinguish from one another clinically.

**Diagnostic Testing.** This condition is mainly diagnosed by physical findings. If used, electrophysiologic studies show evidence of involvement of gluteal muscles or of any muscles innervated by the tibial nerve. This readily distinguishes a partial sciatic mononeuropathy from a lesion of the common peroneal nerve.

**Management.** Treatment of footdrop requires a posterior splint to maintain the ankle at 90 degrees until a brace can be obtained (see the Common Peroneal Mononeuropathy section).

**Lateral Femoral Cutaneous Mononeuropathy**

**Principles.** Lateral femoral cutaneous mononeuropathy (meralgia paresthetica) is a common syndrome believed to be caused by injury to this pure sensory nerve as it passes through or over the inguinal ligament, where it may become entrapped or kinked. Along with facial nerve neuropathy, meralgia paresthetica is one of the most commonly reported mononeuropathies associated with HIV infection.

**Clinical Findings.** Numbness and dysesthesia over the skin of the upper lateral thigh is typically found on physical examination.

**Diagnostic Testing.** There is no diagnostic test for this disease process outside of the physical examination.

**Management.** Regression usually occurs spontaneously, but recurrence is common and may require a release procedure for the inguinal ligament.

**Common Peroneal Mononeuropathy**

**Principles.** The common peroneal nerve is a continuation of one trunk of the sciatic nerve. It is most vulnerable to injury where it winds around the fibular neck (Fig. 97.8). It then passes through the fibular canal and bifurcates into its terminal branches, the superficial and deep peroneal nerves. The superficial peroneal nerve innervates the peroneal muscles (foot everters) and supplies sensation to the lateral, distal lower leg and dorsum of the foot. The deep peroneal nerve traverses the anterior compartment and supplies innervation to the dorsiflexors of the foot and toes plus cutaneous sensation between the first and second toes.

Most common peroneal mononeuropathies are idiopathic and thought to be related to compression where the nerve is superficially located lateral to the fibular neck. Because this common neuropathy is often noted on awakening, it may be secondary to position during sleep. Leg crossing may also be a risk factor for development of this mononeuropathy.

**Clinical Findings.** The most striking feature of a complete common peroneal mononeuropathy is footdrop caused by weakness of foot dorsiflexion. At testing, the everters of the foot are also weak, but the inverters, which are innervated by the tibial nerve, remain strong. This is the single most reliable clinical feature distinguishing sciatic from common peroneal mononeuropathy. Analogous to radial mononeuropathy in the upper
extremity, sensory abnormalities in the leg and foot are inconsistent and easily overlooked in peroneal mononeuropathy.

**Diagnostic Testing.** Most patients with peroneal palsy recover. Those who do not should be studied electrophysiologically to ensure that the point of compression is not proximal to the fibular neck (ie, in the popliteal fossa). If the point of peroneal injury appears to be in the region of or distal to the fibular neck on EMG, patients whose footdrop does not resolve should be considered candidates for exploration to determine whether the nerve is compressed within the fibular canal.

**Management.** Treatment of common peroneal palsy requires a posterior splint to maintain the ankle at 90 degrees until the nerve regenerates. This splinting prevents the foot from falling into sustained equinus (plantar flexion), which in turn allows the intermalleolar distance to narrow, effectively locking the talus out of the ankle mortise.

The treatment of isolated mononeuropathies depends on their etiology, location, and natural history of spontaneous recovery. All penetrating neuropathies should have surgical exploration and repair performed. Blunt trauma may cause a mononeuropathy indirectly by entrapment of a nerve within a fracture, hematoma, or compartment, requiring surgical intervention. Alternatively, nerves may be injured at a point where they are superficial, either by a single direct blow or by sustained pressure caused by immobility (pressure palsies). Most of these resolve spontaneously over time, depending on the severity of injury and length of the nerve. If entrapment can be confirmed by imaging or electrophysiologic studies, a release procedure is indicated. The mononeuropathies that do not require timely surgical exploration should be referred for further evaluation to confirm the location of the neuropathic lesion.

**Type 5: Mononeuropathy Multiplex**

**Principles**

Mononeuropathy multiplex is characterized by an asymmetrical, sensorimotor, usually distal pattern of peripheral neuropathy (Box 97.8). Common causes include vasculitis, diabetes, and Lyme disease.

**Clinical Findings**

As with isolated mononeuropathies, sensory abnormalities tend to be located in the same general anatomic region as the accompanying motor findings. Whether DTRs are affected depends on which nerves are involved. For example, if the process includes the femoral nerve, the patellar reflex is likely to be diminished or absent.

**Lyme Disease.** The PNS manifestations of Lyme disease are divided into early and late. The early PNS syndromes commonly include facial nerve involvement (rarely other cranial nerve palsies) and radiculoneuritis. Late PNS involvement occurs as a DSPN, mononeuropathy multiplex, or radiculoneuropathy. The most common neurologic abnormality in Lyme disease is unilateral or bilateral facial nerve palsy, usually occurring within a month of exposure. Patients may also complain of headache and constitutional symptoms. Early in the course of Lyme disease, severe neuritic pain may develop in a radicular distribution, often in or near the dermatome where the tick bite occurred. There may also be associated sensory changes, motor weakness, and decreased reflexes consistent with nerve root involvement.

Patients with chronic Lyme disease present with sensory symptoms, particularly distal paresthesias in the lower extremities. Less commonly, they develop a picture consistent with mononeuropathy multiplex or a radiculopathy, which is much less severe than the early radiculoneuritis of Lyme disease. The diagnosis and management of Lyme disease is discussed in Chapter 126.

**Diagnostic Testing**

Vasculitis related multiple mononeuropathy is diagnosed with a sural nerve biopsy.

The most useful diagnostic tests for patients with suspected Lyme disease are a serum enzyme-linked immunosorbent assay, Western blot, and CSF examination. CSF abnormalities suggestive of Lyme disease are a lymphocytic pleocytosis, elevated protein level, and normal glucose concentration. The CSF is almost always abnormal in early radiculitis, sometimes abnormal with isolated facial palsy, and typically normal in chronic Lyme disease.

**Management**

Facial nerve palsy in Lyme disease without CSF abnormalities may be treated with oral doxycycline 100 mg twice a day for 2 weeks. Intravenous (IV) ceftriaxone is the drug of choice for all other neurologic syndromes associated with Lyme disease. The adult dosage is 2 g/day, and the pediatric dosage is 75 to 100 mg/kg per day. The standard course of treatment with IV ceftriaxone is at least 2 weeks.

**Type 6: Amyotrophic Lateral Sclerosis**

**Principles**

Although amyotrophic lateral sclerosis (ALS) and motor neuron disease (MND) are often used synonymously, the latter represents a spectrum of diseases ranging from primary lateral sclerosis, in which degeneration is confined to upper motor neurons, to progressive muscle atrophy, in which only lower motor neurons are involved. ALS, which requires the presence of both upper and lower motor neuron findings, resides in the middle of this spectrum, representing the most common form of MND. The incidence of ALS is 1.5 to 2.5 per 100,000. Most develop symptoms in middle-adult life, with motor weakness in the extremities,
The only drug to demonstrate survival benefit in humans with ALS is riluzole, prolonging mean survival from 12 to 15 months. The development of a multidisciplinary team approach has had a much higher impact on overall quality of life for patients with ALS. This team includes ALS-focused neurologists, nurses, occupational therapy, and speech therapy amongst others.

**Type 7: Sensory Neuronopathy (Ganglionopathy)**

**Principles**

This category of peripheral neuropathy is characterized by a selective or predominant involvement of the dorsal root ganglion, producing a relatively pure sensory syndrome analogous to the pure motor syndrome of ALS.

**Clinical Findings**

Although all sensory modalities are affected, proprioception is profoundly altered, leading to sensory ataxia and loss of DTRs without weakness. The distribution is typically asymmetrical and distal at the outset, but depending on severity and extent of progression, it may become functionally symmetrical.

**Diagnostic Testing**

Sensory ganglionopathies can be confirmed by MRI of the spinal cord and surrounding areas, showing degeneration of central sensory projections that localize the disease process to the dorsal root ganglion. Some of the more common causes of this type of peripheral neuropathy are listed in Box 97.10.

**Management**

The management of sensory neuropathies is symptomatic in nature and best left to the patient’s primary physician.
It is not usually possible to arrive at the diagnosis of a specific peripheral neuropathy in the ED because of the need for confirmatory ancillary testing. One should focus on identifying one of seven categorical patterns of peripheral neuropathy, shown in Figure 97.1 and listed in Table 97.1.

One of these seven patterns can usually be identified by combining three clinical features that are readily obtainable from a goal-directed history and physical: (1) right-left symmetry or asymmetry, (2) proximal-distal location, and (3) sensorimotor modalities affected.

Identification of the type of peripheral neuropathy determines the need for ancillary diagnostic testing, therapeutic intervention, disposition, and timing of neurologic referral.

Any patient with symmetrical weakness, distributed both proximally and distally, with loss or diminution of DTRs and variable sensory abnormalities should be treated as having GBS.

Respiratory compromise is the primary life-threatening event seen in some peripheral neuropathies; GBS is by far the most common peripheral neuropathic cause of respiratory arrest.

The definitive treatments for GBS are plasma exchange or intravenous immune globulin (IVIG).

Most polyneuropathies are characterized by a pattern of distal, symmetrical sensorimotor findings, worse in the lower than in the upper extremities, with a stocking-glove distribution of sensory abnormalities that gradually diminishes as one moves proximally.

High level evidence supports the use of tricyclic antidepressants, anticonvulsants, and the serotonin and norepinephrine reuptake inhibitor duloxetine treating diabetic DSPN.

Radial nerve mononeuropathies are characterized by wrist and finger drop and mild numbness over the skin of the first dorsal interosseous muscle.

Humeral shaft fractures are associated with radial nerve injury, with “wrist drop” the hallmark clinical finding.

The ulnar cutaneous innervation to the hand branches from the main trunk proximal to the nerve entering Guyon’s canal thus a lesion at the wrist should not produce sensory abnormalities, whereas one at the elbow would be expected to do so.

The most specific finding for carpal tunnel syndrome (CTS) is splitting of the fourth digit (i.e., normal sensation of the ring finger on the ulnar palmar side with abnormal sensation on the median [radial] palmar side of the same finger).

Lateral femoral cutaneous mononeuropathy (meralgia paresthetica) is caused by injury to this pure sensory nerve as it passes through or over the inguinal ligament, where it may become entrapped or kinked.

The most striking feature of a complete common peroneal mononeuropathy is footdrop caused by weakness of foot dorsiflexion.

The most common neurologic abnormality in Lyme disease is unilateral or bilateral facial nerve palsy, usually occurring within a month of exposure.

ALS requires the presence of both upper and lower motor neuron findings, and is the most common form of motor neuron disease (MND).
97.1. Which category of peripheral neuropathy tends to occur in an asymmetrical, distal distribution?  
A. Autonomic neuropathy  
B. Large-fiber neuropathy  
C. Mixed motor and sensory neuropathy  
D. Neuropathy from vasculitis  
E. Pure motor neuropathy  

Answer: E. Pure motor and pure sensory peripheral neuropathies tend to occur in an asymmetrical distal pattern.

97.2. A 26-year-old woman presents with a chief complaint of weakness. She notes a 1- or 2-day onset of easy fatigability and diminished ability to navigate stairs. She has no past history and takes no medications. Vital signs are normal. Physical examination reveals absent lower extremity deep tendon reflexes (DTRs); symmetrical weakness of the quadriceps, calf muscles, and foot/toe dorsiflexion; and minimal sensory loss. Cranial nerve and upper extremity examination is normal. Which of the following is likely?  
A. An antecedent viral illness  
B. Lack of anal sphincter tone  
C. Onset of ocular muscle dysfunction  
D. Sparing of the autonomic nervous system  
E. Urinary retention  

Answer: A. Guillain-Barré syndrome (GBS) is characterized by fairly acute onset of ascending weakness, loss of deep tendon reflexes (DTRs), and variable sensory loss. Antecedent infections often trigger, with common organisms being campylobacter, cytomegalovirus, Epstein-Barr virus, and mycoplasma. Rarely, symptoms begin in the upper extremities. Urinary retention is common, but anal tone is preserved. Ocular muscles are usually spared. Autonomic neuropathy is common with marked variations in heart rate and blood pressure. Patients with predominantly sensory symptoms tend to have less risk of respiratory embarrassment and a more favorable prognosis. Lumbar puncture shows cerebrospinal fluid (CSF) pleocytosis or may be normal early on.

97.3. A 26-year-old woman presents with lower extremity weakness and difficulty walking. Examination is remarkable for lower extremity symmetrical weakness with mild symmetrical sensory loss and absent lower extremity deep tendon reflexes (DTRs). Symptom onset has been during 2 days. What should be the next step?  
A. Emergent magnetic resonance imaging (MRI)  
B. Intravenous immune globulin (IVIG)  
C. Lumbar puncture and antibiotics  
D. Pulmonary function studies  
E. Urgent neurologic consultation  

Answer: D. All patients with Guillain-Barré syndrome (GBS) are at risk of respiratory failure. A forced vital capacity (FVC) of less than 20 mL/kg and a negative inspiratory force of less than 30 cm H2O are associated with impending ventilatory failure and the need for intubation.

97.4. Among patients with Guillain-Barré syndrome (GBS) who have normal pulmonary function, which of the following can be monitored to predict impending ventilatory failure?  
A. Deltoid strength  
B. Extensor neck strength  
C. Hand grip strength  
D. Masseter strength  
E. Rectus abdominis strength  

Answer: B. Extensor muscle strength has been shown to correlate with ventilatory muscle strength.

97.5. A 53-year-old diabetic presents with a complaint of increasing difficulty walking in the last several months. He has no other past history but has been an insulin-dependent diabetic for 23 years. Current glucose level is 138 mg/dL, and chemistries and complete blood count are otherwise unremarkable. Examination is remarkable for bilateral lower extremity numbness extending symmetrically to above the knees, loss of the Achilles reflex bilaterally with footdrop, and stage 1 gait. Which of the following is true?  
A. Autonomic neuropathy is unlikely  
B. Facial numbness would necessitate MRI  
C. Hand numbness is expected  
D. Erythrocyte sedimentation rate is likely to be elevated  
E. Lumbar spine MRI will likely show a pathologic process.
**Answer:** C. Diabetic neuropathy is a progressive, ascending mixed polyneuropathy. Hand numbness and upper extremity symptoms usually begin before the lower extremity symptoms ascend to the knees. Extensive motor loss can occur with gait and grip abnormalities. Skull and face numbness can occur. Autonomic dysfunction is expected.

97.6. A 53-year-old diabetic presents with increasing symmetrical dysesthetic pain from his well-documented severe diabetic neuropathy. His only medications are insulin and over-the-counter analgesics. Laboratory evaluation is remarkable for a glucose concentration of 183 mg/dL and a creatinine level of 2.1 mg/dL with normal chemistries. Which of the following is indicated as a first-line analgesic in this patient?  
A. Amitriptyline  
B. Hydrocodone with acetaminophen  
C. Naprosyn sodium  
D. Paroxetine  
E. Tramadol  
**Answer:** A. First-line agents for neuropathic pain are the anticonvulsants and cyclic antidepressants. Specifically, gabapentin, pregabalin, amitriptyline, imipramine, and nortriptyline are useful. Tramadol and opiates may be effective but less so. Tramadol is renally excreted (as is gabapentin), and doses must be adjusted for falling creatinine clearances. Nonsteroidal antiinflammatory drugs (NSAIDs) do not have great usefulness for neuropathic pain (there is no “inflammatory” component) and would be contraindicated with elevated creatinine. Opiates may be beneficial, but issues of tolerance are significant. Selective serotonin reuptake inhibitors may be effective but are second-line agents (the norepinephrine-modulating ability of tricyclic antidepressants makes them more effective analgesics than the serotonin-specific agents).

97.7. Which of the following characteristics separates the clinical picture of alcoholic versus diabetic neuropathy?  
A. Autonomic changes  
B. Incontinence  
C. Myopathy  
D. Sensory loss  
E. Weakness  
**Answer:** C. The presence of myopathy and cerebellar degeneration helps distinguish alcoholic neuropathy. Otherwise, the clinical pictures are similar. Incontinence is not a typical feature of either.

97.8. What is the most common neurologic complication of HIV infection?  
A. Autonomic neuropathy  
B. Cerebellar dysfunction  
C. Cranial nerve dysfunction  
D. Peripheral neuropathy  
E. Spinal anterior horn degeneration  
**Answer:** D. It is typically a distal mixed motor and sensory polyneuropathy. It is triggered by a combination of poorly defined immune mechanisms and dideoxynucleoside therapy.

97.9. A 53-year-old woman presents with progressive pain involving her left shoulder and upper arm. She describes a deep aching pain that is poorly localized and is occasionally accompanied by tingling sensations in the left hand in a nondermatomal pattern. Her medical history is negative except for a history of left-sided breast cancer 6 years prior for which she underwent a total mastectomy followed by field irradiation and oral antiestrogen therapy. She currently takes no medications. Review of systems and laboratory results are negative. Physical examination shows only left shoulder dysesthesias. The chest radiograph is normal. What should be the next step?  
A. Computed tomography scan of the chest  
B. Gabapentin in titrated doses  
C. Hydrocodone with acetaminophen and reassurance  
D. MRI scan of the brachial plexus  
E. Referral for upper extremity electromyography (EMG) and nerve conduction studies (NCSs)  
**Answer:** D. Although plexopathies are most commonly posttraumatic, radiation, postviral, and infiltrative processes also occur. In a patient who is status post an oncologic diagnosis and radiation therapy, oncologic recurrence must be ruled out with an imaging study. Radiation plexopathy, which can occur up to 20 years out, is most often a diagnosis of exclusion and ultimately requires symptomatic treatment of neuropathic pain.
**CHAPTER 98**

**Neuromuscular Disorders**

Peter Shearer

---

**PRINCIPLES**

Disorders of the neuromuscular unit can result in clinical presentations that range from subtle symptoms to acute respiratory failure with significant morbidity and mortality. In most cases, the pathophysiologic mechanism of these disorders is well understood and permits an organization and understanding based on the level of the nervous system affected. This facilitates an approach that interprets signs and symptoms, the findings of which direct the urgency of diagnostic testing and treatment.

The neuromuscular unit has four components: the anterior horn cells of the spinal cord, the peripheral nerve, the neuromuscular junction, and the muscle innervated. The level of the pathologic process determines associated signs and symptoms (Fig. 98.1 and Table 98.1). Myelopathies involve the spinal cord; radiculopathies involve the nerve roots as they leave the spinal cord; neuropathies involve the peripheral nerves; and myopathies involve the muscle. The use of physical signs to differentiate these disorders is discussed in Chapter 10.

Neuropathies involve the axon or the myelin sheath of the nerve. Nerve conduction studies can differentiate the locations of involvement. As the conduction along the axon is disrupted, the subsequent delay in transmission first causes symptoms in the muscles controlled by longer nerve axons, resulting in a history of ascending weakness. As the myelin destruction or axonal degeneration progresses, patients usually note a slowly progressive course of symptoms.

The neuromuscular junction is composed of the presynaptic membrane, the postsynaptic membrane, and the synaptic cleft. The neurotransmitter is acetylcholine (ACh). The motor synapse is a nicotinic receptor, whereas muscarinic synapses link the central nervous system (CNS) with the autonomic nervous system. Disorders of the postsynaptic nicotinic receptors produce weakness. Postsynaptic ACh receptors are continually turned over at a rate that is related to the amount of stimulation. A disorder of transmission often leads to increased production of ACh receptors. Myasthenia gravis is the prototype of neuromuscular junction diseases.

**CLINICAL FEATURES**

**History**

The history of patients with complaints of weakness focuses on the acuity and the potential for airway compromise. Any complaint of difficulty in breathing or swallowing raises suspicion of bulbar involvement and concern for life-threatening deterioration. Weakness is the inability to exert normal force, whereas fatigue implies a decrease in force with repetitive use and the clinical history should distinguish which is present. When muscle weakness exists, the clinician should determine whether it is focal or generalized, proximal or distal. The history of present illness should include the duration of symptoms, exacerbating and mitigating factors, and presence of associated symptoms, such as fever, weight loss, and bowel or bladder changes.

Historical elements might explain the presenting complaint: a preexisting neuromuscular disorder that could lead to deterioration; prior episodes or a family history of weakness suggesting periodic paralysis; a recent respiratory or diarrhea illness suggesting a postinfectious, autoimmune process, such as Guillain-Barré syndrome or enterovirus D68, which has been reported to cause muscle weakness and paralysis in children; a cancer history suggesting a metastatic tumor as the cause of a compressive myelopathy; and a food or travel history suggesting botulism or tick exposure.

**Physical Examination**

The examination should first assess the patient’s ability to breathe and ventilate and then evaluate the degree of weakness and the location of the lesion. The presence of swallowing and a strong cough suggest that the patient has sufficient protective and ventilatory reserve. The muscles used to lift the head off the bed may weaken before those of respiration and should be assessed. A patient who is not yet intubated but is complaining of shortness of breath or difficulty in breathing should have frequent measurements of forced vital capacity (FVC). Normal FVC ranges from 60 to 70 mL/kg; when the FVC reaches 15 mL/kg, ventilatory support is necessary. If vital capacity cannot be measured, a maximal negative inspiratory force (NIF) is easily determined. NIF of less than 15 cm H₂O suggests the need for intubation. Blood gas analysis is not helpful because functional reserve can be severely diminished by the time a patient has either hypercarbia or hypoxia.

Some causes of weakness may result in dysregulation of the autonomic system and abnormal vital signs. A systematic neurologic examination assesses the patient’s mental status, cranial nerves, motor and sensory function, deep tendon reflexes, and coordination, including cerebellar function. The motor examination begins by determining whether the weakness is unilateral or bilateral and which muscle groups are involved. Key components of the examination include motor strength, muscle bulk, and presence of fasciculations. Box 98.1 provides the grading system used in motor strength assessment. Table 98.2 provides the findings used to distinguish upper motor neuron from lower motor neuron processes.

**DIFFERENTIAL DIAGNOSIS**

**Myelopathies**

Myelopathies are spinal cord disorders that are manifested with signs of upper motor neuron dysfunction, such as muscle weakness with increased spinal reflexes, including an extensor plantar reflex (Babinski’s response). There may be bladder and bowel involvement. When sensory findings are present, they often define the level of the lesion. The presence of back pain suggests a compressive lesion, such as a herniated intravertebral disk, epidural hematoma, abscess, or tumor. Acute, painless spinal cord lesions include transverse myelitis and spinal cord infarction. Myelopathies are discussed in Chapter 96.
Motor Neuron Disease

The characteristic findings of motor neuron disease combine signs of both upper and lower motor neuron dysfunction, including hyperreflexia, muscle wasting, and fasciculations. Pain is not a component of the clinical picture. Amyotrophic lateral sclerosis is the prototypical motor neuron disease.

Poliomyelitis affects the anterior horn cells and results in lower motor neuron disease without sensory involvement. The weakness can be symmetrical, although more often it is asymmetrical. Patients initially have a clinical picture similar to that of viral meningitis with fever and neck stiffness. Currently, most cases follow exposure of an immunocompromised host to the oral polio vaccine, and this should be sought in the history. The cerebrospinal fluid (CSF) analysis resembles that of viral meningitis.

Neuropathies

Weakness from a neuropathy is often noted first in distal muscles and then ascends. Decreased grip strength and foot drop are common presentations. The differential diagnosis includes Guillain-Barré syndrome, toxic neuropathies, diabetic neuropathy, and tick paralysis (which is caused by inhibition of both nerve conduction and function of the neuromuscular junction). Neuropathies are discussed in Chapter 97.

Diseases of the Neuromuscular Junction

Disorders of the neuromuscular junction cause motor fatigability. The initial depolarization at the nerve endplate stimulates a

*Not significant but can occur.
maximum number of ACh receptors on the muscle cell, producing a normal or nearly normal strength response. Repeated stimulation leads to diminishing motor strength, which is caused by one of three mechanisms: blockage of the receptors, as in myasthenia gravis; decrease in the amount of ACh released, as in botulism; or inactivation of ACh by irreversible binding, as in organophosphate poisoning.

A decrease in the release of ACh can cause a combination of nicotinic and muscarinic effects. The clinical manifestations of this are anticholinergic findings, such as decreased visual acuity, confusion, urinary retention, tachycardia, low-grade fever, and dry, flushed skin. In the case of Lambert–Eaton myasthenic syndrome, weakness is more pronounced at the beginning of muscle use and improves with repeated use as more ACh builds up in the synaptic cleft with each stimulation. Diseases of the neuromuscular junction are considered in patients who present with generalized weakness in association with an acute cranial nerve deficit. Muscle tone is generally diminished and sensation is preserved in diseases of the neuromuscular junction.

**Myopathies**

Myopathies produce generalized, symmetrical weakness. Reflexes are diminished, muscle tone is usually diminished, but sensation is preserved. Myopathies due to inflammatory disorders (polymyositis, dermatomyositis, polymyalgia rheumatica, and viral myositis) cause muscle pain and tenderness. Metabolic disorders affecting muscle strength (eg, electrolyte and endocrine disorders) are painless in nature.

**DIAGNOSTIC TESTING**

**Laboratory Studies**

Serum potassium, calcium, and phosphorus concentrations should be assessed in patients with acute weakness. Thyroid function tests are recommended in cases of suspected myopathies. A creatine kinase (CK) level assesses for muscle inflammation; urinalysis should be performed to test for the presence of myoglobinuria and possible rhabdomyolysis, and renal function studies should be obtained when rhabdomyolysis is present.

**Special Studies**

Magnetic resonance imaging (MRI) is the preferred test for suspected cases of acute myelopathy. Computed tomography (CT) of the spinal cord with myelography can help differentiate compressive (herniation, abscess, tumor) from noncompressive causes when MRI is not available. CSF analysis is indicated when Guillain-Barré syndrome or transverse myelitis is suspected.

**DISORDERS OF THE NEUROMUSCULAR JUNCTION**

**Myasthenia Gravis**

**Principles**

The age at onset of myasthenia gravis is bimodal; women are most commonly affected between 20 and 40 years old and men between 50 and 70 years old. Whereas new cases of myasthenia gravis are occasionally diagnosed in the emergency department (ED), it is much more common for patients with established disease to present with exacerbations of their disorder, often caused by precipitating factors.

In most patients with myasthenia gravis, weakness and fatigue result from circulating autoantibodies against the ACh receptor on the junctional folds on the post synaptic membrane. The effects are multifactorial: direct blocking of the receptor, complement mediated destruction of the folds, and internalization and degradation of the receptors (Fig. 98.2). With repeated stimulation, fewer and fewer receptor sites are available for ACh binding, and fatigue develops. Fatigability and muscle weakness are the hallmarks of myasthenia gravis. The clinical progression of myasthenia gravis is slow, and the likelihood of short-term complications is low, so the most important aspect of emergency care is early recognition and proper referral for further evaluation when the disease is suspected. Many commonly used drugs can adversely affect patients with myasthenia gravis (Box 98.2).

**Myasthenic Crisis.** Myasthenic crisis is defined as respiratory failure leading to mechanical ventilation. It occurs in 15% to 20% of patients with myasthenia gravis, usually within the first 2 years

**Fig. 98.2.** Mechanisms of action of acetylcholine receptor (AChr) autoantibodies. Neuromuscular synapse in myasthenia gravis. AChR antibodies interfere with signal transduction by direct blocking of AChr (A), by cross-linking and increased degradation (B), or by immune mediated destruction including complement activation (C). (From Sommer N, Tackenberg B, Hohlfeld R: The immunopathogenesis of myasthenia gravis. In Engel AG, editor: Handbook of clinical neurology, volume 91, neuromuscular junction disorders, St Louis, 2008, Elsevier, pp 169–212.)

**Drugs That May Exacerbate Myasthenia Gravis**

Cardiovascular
  - Beta-blockers
  - Calcium channel blockers
  - Quinidine
  - Lidocaine
  - Procainamide

Antibiotics
  - Aminoglycosides
  - Tetracyclines
  - Clindamycin
  - Lincomycin
  - Polymyxin B
  - Colistin

Other
  - Phenytoin
  - Neuromuscular blockers
  - Corticosteroids
  - Thyroid replacement
of disease onset. Although it is potentially life-threatening, the mortality from this complication of myasthenia gravis has declined dramatically with aggressive care in the intensive care unit (ICU) and the use of plasma exchange or immunomodulatory therapy with intravenous immune globulin (IVIG).

Crisis TETs are most often precipitated by underlying infection, aspiration, and medication changes, such as stopping anticholinergic medications or taking a new medication that precipitates weakness. Other precipitants can be surgery and pregnancy (see Box 98.2).

Lambert-Eaton Syndrome. Lambert-Eaton myasthenic syndrome is a rare disorder. Almost 50% of cases are associated with small cell carcinoma of the lung. Autoantibodies cause inadequate release of ACh from nerve terminals, affecting both nicotinic and muscarinic receptors. With repeated stimulation, the amount of ACh in the synaptic cleft increases, leading to an increase in strength, which is the opposite of that seen with myasthenia gravis. The classic syndrome includes weakness that improves with use of muscles, particularly proximal hip and shoulder muscles; hyporeflexia; and autonomic dysfunction, most commonly seen as dry mouth. Management primarily focuses on treatment of the underlying neoplastic disorder, although IVIG has been reported to be useful.

Clinical Features

Patients with myasthenia gravis present with easy fatigability—progressive weakness with repeated activity of affected muscle groups. Ocular symptoms are often the first manifestation of myasthenia gravis; typical symptoms are ptosis, diplopia, and blurred vision. Ocular muscle weakness is the first sign in up to 40% of patients, although 85% of patients with myasthenia gravis eventually have ocular involvement. When ptosis is present, it is often worse toward the end of the day. Respiratory failure is rarely the initial symptom of myasthenia gravis. Even so, up to 17% of patients may have weakness of the muscles of respiration. Bulbar muscles may be involved, producing dysarthria or dysphagia.

Diagnostic Testing

The diagnosis of new-onset myasthenia gravis is based on clinical findings and a combination of serologic testing, electromyographic testing, and bedside testing with either edrophonium or the ice bag test. Serum testing for ACh receptor antibodies is positive in 80% to 90% of patients with myasthenia gravis, but it is not available in the ED.

The edrophonium test and ice bag test are performed at the bedside for patients with suspected myasthenia gravis and ptosis. The result is based on the effect of the intervention on the ptosis. Edrophonium is a short-acting acetylcholinesterase-blocking agent that produces an increase of ACh in the synaptic cleft and a reduction in ptosis after intravenous (IV) administration. With the ice bag test, cooling decreases symptoms in myasthenia gravis, whereas heat exacerbates symptoms. In both tests, the amount of ptosis is measured before and after administration of edrophonium or application of an ice bag. The distance from the upper to the lower eyelid in the most severely affected eye is measured first. If edrophonium is given, an IV test dose of 1 to 2 mg is given first because some patients have a severe reaction. If no adverse reaction is found and the patient does not dramatically improve in 30 to 90 seconds, a second dose of 3 mg is given. If there is still no response, a final dose of 5 mg is given for a total maximum dose of 10 mg. Atropine should be available at the bedside during the test. Because of the potential for cholinergic-induced increased airway secretions, this test should be used with caution in asthmatics and patients with chronic obstructive pulmonary disease.

If the ice bag test is used, an ice pack is applied to the affected eye for approximately 2 minutes. An improvement in the amount of ptosis of at least 2 mm is considered positive. The pooled sensitivity and specificity of the ice bag test for detecting ocular myasthenia is 0.94 and 0.97, respectively.

Management

The initial step in managing the patient in crisis is stabilization of the airway. Biphasic positive airway pressure (BiPAP) is effective in managing patients who need ventilatory support.

All patients with myasthenia gravis who present to the ED should be assessed for signs of myasthenic crisis even when they do not complain of weakness.

Cholinesterase Inhibitors. Pyridostigmine (60 to 120 mg by mouth every 4 to 6 hours) and neostigmine (0.5 mg SC/IM) prolong the presence and activity of ACh in the synaptic cleft. They are the backbone of chronic outpatient therapy and provide symptomatic improvement. The most common side effects are those of excessive cholinergic stimulation, such as increased airway secretions and increased bowel motility. At extremes, there may be bradycardia or even worsening of weakness, simulating a myasthenic crisis. These drugs are often used as adjunctive therapy to control symptoms while other therapy is being instituted, after which they are usually discontinued. IV cholinergic drug therapy, such as pyridostigmine, is not recommended for the treatment of myasthenic crises in the ED, because plasmapheresis and IVIG are both safe and highly effective therapies.

Immunosuppressant Drugs. Immunosuppressant drugs are used for the chronic control of myasthenia gravis. Although they have no role in the acute management of a myasthenic crisis, they may be started before extubation of a patient recovering from a crisis. A Cochrane review in 2005 found support for the use of corticosteroids, although cyclosporine, cyclophosphamide, azathioprine, or mycophenolate mofetil are used to decrease the need for steroids or for refractory cases. Of note, the initiation of corticosteroids in patients with moderate to severe weakness may actually precipitate a worsening of weakness or even myasthenic crisis.

Thymectomy. Whereas the association between thymoma and myasthenia gravis is not fully elaborated, it is well known that thymectomy for patients with thymoma can lead to remission of myasthenia gravis or enable a reduction in other medications. Thymectomy for patients with myasthenia gravis without thymoma is recommended as a treatment option, although its use is not supported by randomized controlled trials.

Immunomodulatory Therapy. Plasma exchange and IVIG are used for patients with an acute exacerbation of myasthenia gravis or preoperatively in patients with stable myasthenia gravis. Plasma exchange removes the ACh receptor antibodies and other immune complexes from the blood. The fall in ACh receptor levels is associated with improvement in symptoms of myasthenia gravis. There is a risk of complications from hypotension or anti-coagulation. One small trial of IVIG versus placebo demonstrated the benefit of IVIG, whereas other trials have failed to show a difference between IVIG and plasma exchange. In a cohort of myasthenia gravis patients managed in an ICU over 12 years, 87% were managed with IVIG and only 18% received plasma exchange. In the years preceding this cohort, only 11.4% received IVIG and 60% received plasma exchange reflecting the change in practice patterns. At the current time, the decision to institute one therapy over the other is based on the input of the consulting neurologist and the resources most rapidly available.
Studies suggest that rituximab, a monoclonal antibody that decreases B-cell function, has an emerging role in refractory cases of myasthenia gravis.7 Newer monoclonal antibody therapies directed at the complement mediated destruction of the ACh receptor are under investigation.

Steroids in the form or oral prednisone (1 to 1.5 mg/kg) or prednisolone (1 to 1.5 mg/kg) are often given for acute exacerbations of myasthenia gravis. In the 12-year cohort, above 97% of patients received prednisolone. The evidence supporting the efficacy of corticosteroids is limited.

### Disposition

The decision to admit or to discharge a patient with myasthenia gravis from the ED should take into account the potential for neuromuscular deterioration with consideration of admitting a patient to an observation unit. Patients being admitted to the hospital should have a NIF or FVC measured to help determine the level of monitoring and care needed. These measurements need to be trended during the admission.

### Botulism

#### Principles

Botulism is a toxin-mediated illness that can cause weakness leading to respiratory insufficiency. In 2012, the Centers for Disease Control and Prevention (CDC) reported 160 cases of botulism in the United States: 16% food-borne, 76% infant botulism, 5% wound botulism, and 3% unknown etiology. Clostridium botulinum is an anaerobic, spore-forming bacterium. Three of eight known toxins produced by C. botulinum (types A, B, and E) cause human disease.

There have been outbreaks of wound botulism in Washington, California, England, Germany, and Norway associated with injection drug use.7 In 2011, there was an outbreak among eight prisoners in Utah who drank “pruno,” a prison-made wine.7 Three of the eight required intubation. Botulism is also thought to be a potential agent for bioterrorism.

The botulinum toxin works by binding irreversibly to the presynaptic membrane of peripheral and cranial nerves, inhibiting the release of ACh at the peripheral nerve synapse. As new receptors are generated, the patient improves.

#### Clinical Features

The botulinum toxin blocks both voluntary motor and autonomic functions. There is no pain or sensory deficit. The onset of symptoms is 6 to 48 hours after the ingestion of tainted food. Symptoms of gastroenteritis may or may not be present. The classic feature of botulism is a descending, symmetrical, flaccid paralysis. Cranial nerves and bulbar muscles are affected first, causing diplopia, dysarthria, and dysphagia, followed later by generalized weakness. Because the toxin decreases cholinergic output, anticholinergic signs may be present: constipation, urinary retention, dry skin and eyes, and increased temperature and dilated, non-reactive pupils. This can help differentiate botulism toxicity from myasthenia gravis. Deep tendon reflexes are normal or diminished.

Infantile botulism results from the ingestion of C. botulinum spores that are able to germinate and produce toxin in the high pH of the gastrointestinal tract of infants. Botulism spores can survive in honey, so it is recommended that honey not be fed to infants. The clinical presentation includes constipation, poor feeding, lethargy, and weak cry; consequently, this diagnosis must be included in the differential diagnosis of the floppy infant.

#### Diagnostic Testing

The diagnosis is made by both clinical findings and exclusion of other processes. The toxin can be identified in serum and stool, but the assay is not commonly available in most hospitals and requires a prolonged turnaround time. If the suspected food source is available, it should also be tested for the toxin.

#### Management

Treatment is initially focused on stabilization of the airway and supportive measures. In 2010, the CDC announced a new equine heptavalent botulinum antitoxin (HBAT) that is now the only antitoxin available in the United States for non-infant botulism.8 For suspected cases and to obtain HBAT, clinicians should contact their state health departments. The CDC also maintains a botulism duty officer at the CDC Emergency Operations Center (770-488-7100). An IV human-derived botulism immune globulin (BabyBIG) has been developed for treatment of infantile botulism and is available through the California Department of Public Health Infant Botulism Treatment and Prevention Program on-call physician at 510-231-7600.

#### Disposition

All patients being treated for botulism need to be hospitalized, and most will be admitted to an ICU setting given the likelihood of progression of neuromuscular weakness. Infants and children will need to be transferred to the most appropriate neonatal intensive care unit (NICU) or pediatric intensive care unit (PICU) setting.

### Tick Paralysis

#### Principles

This extraordinarily rare cause of an acute, ascending, flaccid paralysis is most often found in North America (Rocky Mountain region, US Pacific Northwest, and Southwestern Canada) and the east coast of Australia. Although the pathogenesis of tick paralysis is not fully understood, it is thought that a salivary toxin is injected while the tick feeds. The toxin functions like botulinum toxin to decrease the release of ACh from the presynaptic membrane of the neuromuscular junction.9

#### Clinical Features

Tick paralysis causes an acute, ascending, flaccid motor paralysis that can be confused with Guillain-Barré syndrome, botulism, and myasthenia gravis. Symptoms usually begin 1 to 2 days after the female tick has attached and begun to feed, although delays of up to 6 days have been reported. There may be associated ocular signs, such as fixed and dilated pupils, that can help distinguish it from Guillain-Barré syndrome.

#### Management

The management is supportive care and tick removal. A tick can be removed by use of forceps to grasp it as closely as possible to the point of attachment. Care should be taken not to leave mouth parts in the patient’s tissue. Although symptoms may resolve rapidly after removal of the tick, supportive measures such as intubation should not be withheld pending resolution of symptoms. Although there is little new research on the topic, there are many reports of cases misdiagnosed as other causes of weakness (Guillain-Barré syndrome, acute inflammatory demyelinating
polyneuropathy, and so on) until the offending tick is found and removed.

Disposition
These patients may begin to show improvement upon removal of the tick and may be able to be discharged from the ED. There should be strong consideration of admission to an observation unit if the patient is slow to improve.

DISORDERS OF THE MUSCLES

Newly acquired weakness originating at the muscle level can be divided into two types: inflammatory and toxic-metabolic. Inflammatory disorders usually produce pain and tenderness, whereas metabolic disorders do not.

Inflammatory Disorders

Principles
The most common inflammatory myopathies are polymyositis and dermatomyositis. Polymyositis may be idiopathic in nature, occur secondary to infections (viral or bacterial), or be seen in conjunction with other disorders, such as sarcoidosis and hypersinophilic syndromes. Inflammatory myopathies cause weakness, pain, and tenderness of the muscles involved.

Clinical Features
Dermatomyositis and polymyositis can occur at any age, although adults are more often affected than children. They can be associated with various malignant neoplasms, such as of the breast, ovary, lung, and gastrointestinal tract, and lymphoproliferative disorders. Proximal muscle weakness predominates and leads to complaints of difficulty in rising from a seated position or climbing stairs and weakness in lifting the arms over the head. There is often pain and tenderness in these proximal muscles as well. There is a decrease in reflexes that is in proportion to the decrease in strength. Fasciculations are not seen, and atrophy is a very late finding.

Dermatomyositis is similar to polymyositis, but it is also associated with classic skin findings. These are more prominent in childhood but are also found in adults. They include a periorbital heliotrope and erythema and swelling of the extensor surfaces of joints. The facial rash is usually photosensitive and may also involve the exposed areas of the chest and neck.

Diagnostic Testing
Electrolyte abnormalities must be ruled out and the serum CK level checked. The CK level should be interpreted in light of the entire clinical picture; an elevated CK level does not establish the cause of weakness as a myopathy because some neuropathies can also produce an elevated CK level. Similarly, a normal CK level does not rule out a myopathy as the cause of weakness. Electromyography and muscle biopsy are used to confirm the diagnosis. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often normal or only mildly elevated; thus they have no role in diagnosis or prognosis.

Management
Polymyositis and dermatomyositis are usually managed with oral prednisone in a dose of 1 to 2 mg/kg/day. When steroids prove ineffective and during acute exacerbations, cytotoxic drugs such as azathioprine (initial dose of 50 mg/day) and methotrexate (initial dose of 15 mg/week) are added. Fortunately, the degree of rhabdomyolysis seen with the inflammatory myopathies is not sufficient to cause renal impairment.

Disposition
The majority of these patients will likely be discharged, some following an observation period. Hospitalization should be considered for patients with comorbidities, elders, and those who do not improve with treatment in the ED or observation unit.

Metabolic Disorders

Acute, generalized muscle weakness can be seen with a number of severe electrolyte abnormalities of any cause: hypokalemia, hyperkalemia, hypocalcemia, hypercalcemia, hypomagnesemia, and hypophosphatemia. Acute painless myopathies can also be seen with endocrine disorders involving the thyroid, parathyroid, or adrenal glands.

Of particular interest are several disorders referred to collectively as the periodic paralyses, which include periodic paralysis of the hyperkalemic and hypokalemic forms and thyrotoxic periodic paralysis, which is similar to hypokalemic periodic paralysis except that it is associated with hyperthyroidism.

Periodic Paralysis

Principles. Periodic paralysis of the hypo- and hyperkalemic forms are rare hereditary disorders of ion channels resulting in intermittent attacks of flaccid extremity weakness. The hypokalemic form is more common than the hyperkalemic form. Periodic paralysis is most often associated with an inherited genetic mutation. Patients usually report a personal and family history of similar episodes. Thyrotoxic periodic paralysis is an acquired rather than inherited form of hypokalemic periodic paralysis.

The clinical picture of thyrotoxic periodic paralysis is almost identical to that of periodic paralysis, and indeed a small number of patients with hypokalemic periodic paralysis have hyperthyroidism. In thyrotoxic periodic paralysis, symptoms related to hyperthyroidism are often present at the same time the patient has weakness. The relation of the hyperthyroidism to hypokalemic periodic paralysis is probably due to increased sodium-potassium adenosine triphosphatase (Na+/K+–ATPase) pump, which causes a rapid shift of potassium from the extracellular into the intracellular compartment. There is probably a genetic feature underlying this disorder, because there is a higher incidence of repeated attacks of hypokalemic periodic paralysis among Japanese and Chinese patients with hyperthyroidism. It is important that all patients have thyroid function testing performed after a first episode of hypokalemic paralysis.

Clinical Features. Patients may suffer either isolated or recurrent episodes of flaccid paralysis. The lower limbs are involved more often than the upper, although both can be affected. Bulbar, ocular, and respiratory muscles are usually not involved. Onset is often following a high oral carbohydrate intake (with subsequent insulin rise) and a period of rest. This reflects the intracellular shift of potassium rather than the total body depletion of potassium. A typical complaint is acute weakness noted on waking the morning after a large meal.

Diagnostic Testing. The electrocardiogram may demonstrate signs of hyperkalemia or hypokalemia. An immediate determination of potassium level should be obtained; in the hypokalemic form, the potassium level during an attack falls to values well below 3.0 mEq/L.
Management. Many cases resolve spontaneously with supportive care alone. The mainstay of management is the treatment of the underlying electrolyte imbalance. In the hypokalemic state, the total body potassium concentration is not depleted but has shifted intracellularly. Thus, in the repletion of potassium, caution is necessary to prevent overtreatment. For this reason, IV potassium should be used sparingly; one or two 10-mEq IV doses of potassium chloride, each over 1 hour, is the maximum IV dose. This can be done in parallel with 40 mEq oral potassium repletion and retesting of serum potassium levels. IV hydration helps redistribute the body’s potassium stores. Magnesium supplementation is not necessary. Treatment of the hyperthyroid symptoms in thyrotoxic periodic paralysis, such as tachycardia, may help the paralysis as well. There are case reports of thyrotoxic periodic paralysis in which the patient’s weakness did not respond to potassium replacement until propranolol was given to treat tachycardia. However, there is insufficient evidence to make specific management recommendations in this regard.

Disposition. In the past, most cases of periodic paralysis needed to be hospitalized, but with the increased availability of observation units they can likely be managed in less than 24 hours. Admission can be considered for patients with their first episode of periodic paralysis for patients needing management of thyrotoxicosis.

KEY CONCEPTS

- The approach to evaluation of patients with acute neuromuscular weakness is facilitated by first determining the location of the lesion (spinal cord, nerve, neuromuscular junction, or muscle) and then considering the most common disorders that affect the area in question.
- In patients presenting with acute neuromuscular weakness, complaints of difficulty in breathing or swallowing should heighten suspicion of bulbar involvement with possible airway compromise. In such patients, FVC of less than 15 mL/kg or maximal NIF of less than 15 mm H₂O is a potential indication for mechanical ventilation.
- Patients with a neuromuscular decline in respiratory function can be given a trial of noninvasive ventilation.
- The edrophonium and ice bag tests can be useful bedside tests in the evaluation of a suspected new diagnosis of myasthenia gravis.
- Plasma exchange therapy and IVIG are both useful for the treatment of myasthenic crises with the choice dependent on which is available and preferred in the ICU.
- Botulism usually arises as a painless descending paralysis, often first affecting the cranial nerves and bulbar muscles, without sensory deficits or significant alteration of consciousness. The treatment is airway management and administration of antitoxin.
- Injection drug use remains an important cause of wound botulism outbreaks.
- Botulism must be considered in the evaluation of a weak and floppy infant.
- In hypokalemic periodic paralysis, the total body potassium level is not depleted, only shifted intracellularly: treatment should keep this in mind as potassium is administered with frequent checks of serum potassium levels.
- In newly diagnosed hypokalemic periodic paralysis, the patient should be evaluated and treated for hyperthyroidism if present.

CHAPTER 98: QUESTIONS & ANSWERS

98.1. Which of the following is an indication for intubation in a 70-kg patient with weakness due to neuromuscular disease?
   A. Arterial PaCO₂ of 42 mm Hg
   B. Forced vital capacity (FVC) of 950 mL
   C. Negative inspiratory force (NIF) of 18 mm Hg
   D. Oxygen saturation of 95% on room air
   E. Respiratory rate of 24 breaths per minute

Answer: B. An FVC less than 15 mL/kg or an NIF less than 15 mm Hg are indications for intubations. Regarding arterial blood gas analysis, functional reserve can be severely diminished by the time a patient develops hypoxia or hypercarbia.

98.2. Match the following pathologic conditions with their correct associated finding(s):
   A. Motor neuron disease—upper/lower motor neuron findings
   B. Myelopathy—preserved sensation
   C. Myopathy—distal weakness that ascends
   D. Neuromuscular junction disease—Babinski’s response
   E. Neuropathy—acute cranial nerve deficit

Answer: A. Amyotrophic lateral sclerosis (ALS) and polio are the classic cases of motor neuron disease. The typical presentation is a mix of upper and lower motor neuron findings. The following are other correct associations:
Myopathy—preserved sensation
Neuromuscular junction disease—acute cranial nerve deficit
Myelopathy—Babinski’s response
Neuropathy—distal weakness that ascends

98.3. You have intubated a patient in myasthenic crisis but do not have plasmapheresis immediately available in your hospital. Your next choice of therapy would be:
   A. Begin intravenous (IV) pyridostigmine
   B. Begin IV immune globulin 1 g/kg daily
   C. Edrophonium 1 mg IV test dose followed by 3–5 mg IV
   D. Start rituximab

Answer: B. Although evidence supporting IV immune globulin is weak, it is an accepted alternative to plasmapheresis. Pyridostigmine and neostigmine are used orally for maintenance and not for acute crisis, and the IV dose might cause complications from the cholinergic excess, such as increased secretions.

98.4. A 24-year-old Mexican male presents with hypokalemic periodic paralysis. His potassium level is 1.6 mEq/L. After receiving 2 L of normal saline IV and KCl 30 mEq IV over 3 hours, his vital signs are blood pressure 178/96, heart rate 126, temperature 38°C, and respiratory rate 16. His weakness is not improving. What is the most appropriate next therapeutic option?
   A. KCl 20 mEq IV bolus
   B. Plasmapheresis
   C. Prophylactic intubation for airway protection
   D. Propranolol 40 mg by mouth

Answer: D. For patients with thyrotoxic periodic paralysis, the weakness often does not correct if the hyperthyroid state is not treated along with the hypokalemia. Thyrotoxic periodic paralysis is more common in Japanese and Hispanic men. Such patients also do not usually manifest paralysis unless their potassium level drops while they are hyperthyroid.
Overview

Meningitis is an inflammation of the membranes of the brain or spinal cord and is also called arachnoiditis or leptomeningitis. Encephalitis denotes inflammation of the brain itself; myelitis refers to inflammation of the spinal cord. The terms meningoencephalitis and encephalomyelitis describe more diffuse inflammatory processes. Collections of infective and purulent materials may form within the central nervous system (CNS) as abscesses. Brain abscesses may be intraparenchymal, in epidural or subdural intracranial locations, or may be found in intramedullary or epidural spinal locations.

The etiologic spectrum of CNS infection has changed considerably as a result of the development and use of antibiotics and the epidemic emergence of diseases and conditions that impair the immune system (eg, human immunodeficiency virus [HIV]). Likewise, diagnostic tools have been developed that allow precise pathogen identification, including polymerase chain reaction (PCR) tests for viral nucleic acids in cerebrospinal fluid (CSF). The use of pneumococcal, Haemophilus influenzae type b (Hib), and meningococcal vaccines has led to dramatic reductions in the incidence of meningitis. Unfortunately, despite advances, the morbidity and mortality of these disorders remain considerable.

Bacterial Meningitis

Meningeal inflammation may be caused by a variety of disease processes, but infectious etiologies predominate. Common pathogens of CNS infections are Streptococcus pneumoniae, Neisseria meningitidis, Listeria monocytogenes, and H. influenza. Although the incidence of S. pneumoniae has declined, it remains the predominant pathogen in adult patients, followed by N. meningitidis and L. monocytogenes. N. meningitidis is the predominant organism in adults younger than 45 years old.

Five major serogroups cause most meningococcal disease worldwide (A, B, C, Y, and W-135). Serogroup A accounts for the majority of cases of meningococcal meningitis in developing nations. A new vaccine for serogroup A may potentially reduce the impact of this disease in nearly half a billion individuals at risk. Serogroup distribution for invasive disease has changed markedly in the United States, with B, C, and Y now most common. Interestingly, higher case fatality has been observed in N. meningitidis outbreaks versus sporadic cases, likely due to increased virulence of outbreak-related strains.

Meningeal infection may also occur in association with a dual leak secondary to neurosurgery or neurotrauma. S. pneumoniae, Staphylococcus aureus, Pseudomonas aeruginosa, and coliform bacteria are seen most commonly in this population.

The pathogenetic sequence in bacterial meningitis generally begins with nasopharyngeal colonization and mucosal invasion. Virulent microbes secrete immunoglobulin A proteases, induce ciliostasis of mucosal cells, and survive intravascularly by evasion of the complement pathway. The varying capsular properties of each organism protect the bacteria. Once bacteria cross the blood-brain barrier to enter the CSF, host defense mechanisms within the CSF are often ineffective due to low levels of complement, immunoglobulin, and opsonic activity. Bacterial proliferation then occurs, which stimulates a convergence of leukocytes into the CSF.

Meningeal and subarachnoid space inflammation is associated with the release of cytokines into the CSF, most notably tumor necrosis factor and interleukins 1 and 6. These cytokines incite an inflammatory cascade that promotes increased permeability of the blood-brain barrier, cerebral vasculitis, edema, and increased intracranial pressure (ICP). A subsequent decrease in cerebral blood flow leads to cerebral hypoxia. Glucose transport into the CSF is decreased concomitantly with increased glucose utilization resulting in cellular metabolic failure.

The case fatality rate for pneumococcal meningitis has improved and is less than 20%, with higher fatality rates occurring in patients with serious underlying disease or advanced age. The prognosis is related to the degree of neurological impairment on presentation. Overall, 20% to 30% of the survivors of pneumococcal meningitis have some residual neurological deficit. The case fatality rate for Listeria meningitis may be as high as 40%.

Tuberculous Meningitis

Death from tuberculous meningitis in the adult age group ranges from 10% to 50% of cases, with the incidence directly proportional to the patient’s age and the duration of symptoms before presentation. Focal ischemic stroke may result from the associated cerebral vasculitis. In advanced disease, up to 25% of patients may require some neurological procedure for obstruction (ventriculoperitoneal shunt or drainage). In most patients some neurological deficit develops, but severe long-term sequelae among survivors are unusual.

Viral Meningitis and Encephalitis

The actual incidence of viral meningitis is unknown because most cases go unreported. A prominent increase of cases is seen in summer months, which is concurrent with seasonal predominance of the enterovirus group of the picornaviruses. The same organisms responsible for viral meningitis may also be associated with encephalitis. A common mechanism of transmission is via insect vectors; arbovirus infection is an example, although clinical disease develops in only a small percentage of the people bitten. Herpetic encephalitis is believed to occur via direct neuronal transmission from a peripheral site via a cranial nerve. Viruses enter the human host through the skin (ie, insect vectors); through the respiratory, gastrointestinal, or urogenital tract; or by receipt of infected blood products or donor organs. Viral replication subsequently occurs outside the CNS, most often followed by hematogenous spread to the CNS. Additional routes into the CNS include retrograde transmission along neuronal axons and direct invasion of the subarachnoid space after infection of the olfactory submucosa.

The development of a viral CNS infection is linked to the virulence of the specific virus, the viral inoculum level, and the state
of immunity of the human host. The tropism of the virus for specific CNS cell types also influences the locality of disease and its manifestations. Particular viruses may preferentially attack cortical, limbic, or spinal neurons, oligodendria, or ependymal cells. An example is the tropism of herpes simplex virus (HSV) for the temporal lobes and the development of temporal lobe seizures and behavioral changes in afflicted patients.

With rare exceptions, the overall prognosis for complete recovery from viral meningitis is excellent. Various complications related to the systemic effects of the particular virus include orchitis, parotitis, pancreatitis, and various dermatoses. Usually all of these complications resolve without sequelae. Interestingly, HSV meningitis is often associated with the initial outbreak of genital herpes, and in contrast to HSV encephalitis the outcome is usually good.

The outcomes in viral encephalitis are dependent on the infecting agent. The mortality from HSV encephalitis before the use of acyclovir was 60% to 70%. Acyclovir treatment has reduced the mortality to approximately 30%. Common complications observed among survivors include seizures, motor deficits, and changes in mentation. Encephalitis caused by Japanese encephalitis virus, Eastern equine virus, and St. Louis encephalitis virus is severe, with high mortality rates and virtually universal neurological sequelae among survivors. West Nile virus produces encephalitis in only 0.5% of those infected, yet it resulted in 120 deaths in 2003. Western equine virus and California encephalitis virus cause milder infections, and death is rare. The incidence of neurological sequelae is highly variable and appears to depend on both the host and the infecting agent. Tickborne encephalitis is endemic to parts of Europe and is an important consideration for residents and recent travelers to those regions. Reports of influenza A H1N1 encephalitis in adults have emerged, which bear striking resemblance to “encephalitis lethargica” reported as a complication of encephalitis in adults have emerged, which bear striking resemblance to “encephalitis lethargica” reported as a complication of influenza like illnesses in the 1920s.

Although post-infectious encephalomyelitis (PIE) is not directly caused by CNS invasion of the measles virus, it is useful to consider the complications of PIE. Predominantly affecting adolescents, up to one quarter of measles patients with PIE will die, and many survivors have dramatic neurological sequelae and permanent disability; this process appears mediated by an immune system response that attacks myelin basic protein. The flaccid paralysis associated with enterovirus D68 left some affected children with permanent deficits similar to polio.

Fungal Meningitis
Fungal meningitis probably develops in much the same way as bacterial meningitis, although this has been incompletely studied. Pulmonary exposure followed by hematogenous spread is the primary pathogenic mechanism in most cases. Immune system defects or immunosuppressive medications compromise host defense mechanisms, with ensuing development of CNS infection. Congenital infections, intravenous (IV) drug use, neurological surgery, and cranial trauma. Brain abscess secondary to otitis media most often occurs in pediatric or older adult populations. When associated with sinusitis, it most often arises among young adults. Increasingly, CNS abscesses are seen in the immunocompromised population, particularly those with HIV infection, and among bone marrow and solid organ transplant recipients. However, antimicrobial prophylaxis in immunosuppressed patients and more aggressive treatment of otitis and sinusitis have decreased the incidence of CNS abscesses.

Intraparenchymal brain abscesses, subdural empyema, or intracranial or spinal epidural abscesses result from inoculation of the CNS from either contiguous spread of organisms from a sinus, middle ear, or dental infection, or from metastatic seeding from a distant site (eg, a pulmonary infection or endocarditis). The primary infection can be identified in 75% to 85% of cases. These conditions may also follow surgery or penetrating cranial trauma, particularly when bone fragments are retained in brain tissue. Otogenic abscesses occur most commonly in the temporal lobe in adults and cerebellum in children, whereas sinogenic abscesses typically occur in frontal areas. Multiple brain abscesses suggest hematogenous spread of organisms, most commonly from the pulmonary system, although solitary lesions may also occur (Fig. 99.1).

The mortality rate from brain abscess has declined dramatically from approximately 50% to less than 20% due to a number of factors including early diagnosis afforded by the use of the cranial computed tomography (CT) scan; improved antimicrobial therapy; and combined management approaches with surgery, aspiration, and medical therapy.

**CLINICAL FEATURES**

**Meningitis**

Numerous host factors have been implicated in the acquisition of meningitis, although disease also occurs when none are present.
PART III

1330

PART III Medicine and Surgery | SECTION SEVEN Neurology

BOX 99.1

Host Factors Predisposing to Meningitis

- Age younger than 5 years old
- Age older than 60 years old
- Male gender
- Low socioeconomic status
- Crowding (e.g., military recruits)
- Spleenectomy
- Sickle cell disease
- African-American race
- Alcoholism and cirrhosis
- Diabetes
- Immunologic defects
- Recent colonization
- Dural defect (e.g., traumatic, surgical, congenital)
- Continuous infection (e.g., sinusitis)
- Household contact with meningitis patient
- Thalassemia major
- Intravenous (IV) drug abuse
- Bacterial endocarditis
- Ventriculoperitoneal shunt
- Malignancy

(Box 99.1). The constellation of symptoms that may classically occur in an acute CNS infection consists of fever, headache, photophobia, nuchal rigidity, lethargy, malaise, altered sensorium, seizures, vomiting, and chills. Unfortunately, subtle presentations are also common especially in immunosuppressed and geriatric patients where an alternation in mental status may be the only finding. However, good quality literature suggests that the absence of fever, stiff neck, and mental status change excludes meningitis in immunocompetent adults. A systematic review of prospective data in children found clinical factors useful in increasing the likelihood of bacterial meningitis included bulging fontanel, neck stiffness, and seizures in children outside the age typical for febrile convulsions. No combination of factors have been identified that rule in or rule out the disease, which is not surprising given the diversity of presentations in children.

The presentation of fungal meningitis can be obscure even in the healthy adult population. Headache, low-grade fever, lassitude, and weight loss may be present but often to such a mild degree that the correct diagnosis is not initially considered. This is also true of tuberculous meningitis, which often has a protracted course and a vague nonspecific presentation consisting of fever, weight loss, night sweats, and malaise, with or without headache and meningismus.

The physical findings in meningitis vary, depending on the host, causative organism, and severity of the illness. Kernig’s sign (inability to straighten leg to a position of full knee extension when patient is lying supine with hip flexed to a right angle) and Brudzinski’s sign (attempts to flex the neck passively are accompanied by flexion of the hips) are present in approximately 50% of adults. When patients with suspected meningitis were evaluated, the sensitivity of Kernig’s sign, Brudzinski’s sign, and the presence of nuchal rigidity are 5%, 5%, and 30%, respectively, suggesting that these physical findings have limited diagnostic value. On the other hand, at least in children, the 2010 National Institute for Health and Clinical Excellence guidelines found that 85% to 95% of children with meningitis had fever, 66% had Brudzinski’s sign, 53% had Kernig’s sign or neck stiffness, and 83% had at least one of the three objective findings. Deep tendon reflexes may be increased, and ophthalmoplegia may be present, especially of the lateral rectus muscles. Papilledema, if observed, or lack of venous pulsations, are consistent with increased ICP and should raise the concern for a structural lesion. In addition, patients with coma (Glasgow Coma Score [GCS] of <9) should not undergo lumbar puncture (LP) due to risk for herniation.

The systemic findings in meningitis may include an obvious source of infection, such as sinusitis, otitis media, mastoiditis, pneumonia, or urinary tract infection. Various manifestations of endocarditis may be present. Arthritis may be seen with N. meningitidis and occasionally with other bacteria. Petechiae and cutaneous hemorrhages are widely reported with meningococcal meningitis but also occur with Hib, pneumococcal organisms, L. monocytogenes, and echovirus infections, in addition to staphylococcal endocarditis. Endotoxic shock with vascular collapse often develops in severe meningococcal disease, but shock may be present in the advanced stages of any bacterial meningitis. Any determination of a serious systemic infection should encourage rather than dissuade the clinician from considering the possibility of a concomitant CNS infection.

The immediate and delayed complications of bacterial meningitis are presented in Box 99.2. The incidence of bilateral adrenal hemorrhage (Waterhouse-Friderichsen syndrome) is dramatically higher when meningococccemia is present. Hydrocephalus may develop in as many as 5% of patients with community acquired meningitis; and when this is present on admission, the proportion dead or with an unfavorable outcome approaches 50% to 70%. Delayed cerebral venous thrombosis can occur in patients who appear to initially have a full recovery from pneumococcal meningitis, suggesting an immunologic vasculopathy.

BOX 99.2

Complications of Bacterial Meningitis

### IMMEDIATE
- Coma
- Loss of airway reflexes
- Seizures
- Cerebral edema
- Vasomotor collapse
- Disseminated intravascular coagulation (DIC)
- Respiratory arrest
- Dehydration
- Pericardial effusion
- Death
- Others

### DELAYED
- Seizure disorder
- Focal paralysis
- Subdural effusion
- Hydrocephalus
- Intellectual deficits
- Sensorineural hearing loss
- Ataxia
- Blindness
- Bilateral adrenal hemorrhage
- Death
- Cerebral venous thrombosis
- Others

Viral Encephalitis

Patients with encephalitis may also have symptoms of meningeval irritation. An alteration of consciousness or delirium occurs in virtually all patients. Fever, headache, personality changes, confusion, and disorientation are also usually present. Hallucinations and bizarre behavior may precede motor, reflex, and other neurological manifestations by several days, occasionally prompting an

Seizures
initial diagnosis of a psychiatric disorder. Because focal neurological deficits and seizures occur much more commonly with encephalitis than meningitis, early neuroimaging is indicated to assess for a brain abscess. Distinguishing the etiologic agent in encephalitis is clinically difficult, although HSV encephalitis results in a higher incidence of dysphasia and seizures relative to the other viral encephalitides. In some patients, West Nile virus produces a myelitis that affects the anterior horn cells of the spinal column, resulting in a flaccid paralysis with a clear sensorium, similar to findings in polio or Guillain-Barré syndrome. A thorough skin and mucosal examination is important to assess for the presence of herpetic lesions.

Central Nervous System Abscess

Seizures are the most common complication of an intracranial abscess, occurring in 80% of patients. Other neurological findings of intracranial abscesses, including focal motor or sensory deficits or changes in mentation, are common. Complications of a spinal abscess primarily result from cord compression, including paralysis, motor and sensory deficits, and bowel and bladder dysfunction. Patients with an intracranial abscess may be indistinguishable from those with meningitis or encephalitis at the bedside. Most patients with intraparenchymal abscess have a subacute clinical course with symptoms progressing over 2 or more weeks. Nuchal rigidity and fever are present in fewer than 50% of cases. Focal neurological deficits are often present; however, easier access to advanced imaging is facilitating earlier diagnosis before focal deficits become manifest.

Generally, the neurological symptoms associated with brain abscess will localize to the affected areas of the brain. An abrupt neurological deterioration can result from uncal herniation or abscess rupture into the ventricular system. Similar to the subacute presentation of brain tumors, subtle motor deficits, memory changes, or localized seizures are more common than the abrupt deficits observed with acute stroke.

Patients with a subdural or epidural abscess often have headache, fever, and focal deficits. Most of the patients with spinal abscess typically present with spinal pain and other symptoms and signs of cord compression.

Differential Diagnosis

Patients with meningitis may have symptoms and signs ranging from mild headache with fever to frank coma and shock. To facilitate the discussion of diagnosis and treatment, meningitis may be divided into three clinical syndromes based on timing: acute meningitis, subacute meningitis, and chronic meningitis.

Acute meningitis encompasses patients with obvious signs and symptoms of meningitis who are evaluated in less than 24 hours after the onset of their symptoms and who rapidly deteriorate. In many of these patients, the diagnosis of meningitis is not in doubt, and the crucial step is to initiate antimicrobial therapy immediately. The most likely pathogens in this syndrome are S. pneumoniae and N. meningitidis. Although H. influenzae has been reported in this context, it is not commonly implicated in the adult population. In this scenario, with abrupt onset, the most important differential diagnostic considerations are viral meningitis, acute subarachnoid hemorrhage (SAH), and acute cranio-cervical arterial dissection.

Distinguishing between viral and bacterial meningitis is challenging and described in more depth in the Diagnostic Testing section. Because subarachnoid blood is quite irritating to the meninges, it will cause neck pain when it migrates through the foramen magnum; it is distinguished from meningitis using CT imaging or LP. Generally, SAH and dissection will not have associated infectious symptoms and signs, such as a prodrome or fever.

In the syndrome of subacute meningitis, the symptoms and signs causing the patient to seek care have developed during a period of 1 to 7 days. This syndrome includes virtually all cases of viral meningitis, along with most of the bacterial and some of the fungal etiologies. The differential diagnosis depends on the symptoms and signs at presentation. Brain tumor and drug effects or toxicities are important considerations. Conversely, care must be taken to avoid early diagnostic closure, particularly in the elders and immunosuppressed individuals; for example, even when a fever is present, a patient’s change in mental status may be misattributed to another disease outside the CNS, such as pneumonia or urinary tract infection; neck stiffness may be misattributed to degenerative joint disease.

The differential diagnosis of encephalitis and brain abscess occurs in the context of the subacute meningitis syndrome. Brain abscess should be considered, especially if fever is minimal or absent or if there are focal neurological findings. In addition, diagnoses such as subdural empyema, brain tumor, SAH, subdural hematoma, and traumatic intracranial hemorrhage should be considered. Non-convulsive status epilepticus is a consideration in patients with altered mental status especially if there is a seizure history or a known structural brain lesion.

The spectrum of chronic meningitis includes the viral meningitides, as well as meningitis caused by tubercle bacilli, syphilis, and fungi. Many of the patients in this group have had symptoms for at least 1 week before presentation and generally have a prolonged indolent course marked by difficult and changing diagnoses and multiple therapies. Causes of aseptic meningitis—simply defined as all cases with negative bacterial CSF cultures—are listed in Box 99.3.33

Spinal epidural abscess should be suspected in patients with sudden, atraumatic back pain. Of particular concern are patients with spinal surgery and instrumentation, IV drug abuse, and immunosuppression. Thoracic dissection or pulmonary embolism are two critical diagnoses that must be considered in these patients. Spinal epidural hematoma is another concern, particularly in patients who are anticoagulated. Some lesions as high as the cervical spine may only manifest symptoms in the lower extremities; spinal epidural abscesses in the mid thoracic spine mimicking cauda equina syndrome have been reported.

Diagnostic Testing

Laboratory Testing

As with other infectious diseases, the complete blood count (CBC) with differential diagnosis is a nonspecific adjunct in the diagnostic evaluation of a patient suspected to have a CNS infection. The peripheral cell counts are often normal in the presence of significant disease and may even be depressed, particularly in elders or immunosuppressed persons. A “normal” leukocyte count and differential diagnosis should not dissuade the clinician from pursuing the diagnosis of a CNS infection. Procalcitonin is emerging as a promising serum marker of serious bacterial infections, and it may help to discriminate between bacterial and viral etiologies of meningitis and to track response to therapy. However, the test needs more study before it can be recommended as a marker to exclude meningitis.10,11

Serum electrolytes, glucose, urea nitrogen, and creatinine levels should be measured to facilitate the interpretation of the CSF glucose level and to establish the level of renal function and the state of electrolyte balance.

Two or three blood cultures should be obtained for all patients who are being evaluated for a CNS infection, even when antimicrobial therapy has already been administered. The blood cultures can improve the identification of the causative organisms, especially with pneumococcus and, to a lesser degree, meningococcus.
infection in whom there is the possibility of an intracranial abscess, intracranial hemorrhage, or mass lesion. However, neuroimaging should not unnecessarily delay LP or antimicrobial therapy. More than 50% of neuroimaging studies in acute meningitis show no specific abnormalities.

The CT scan may show hypodense lesions in the temporal lobes in patients with HSV encephalitis, although an MRI scan reveals this abnormality much earlier in the disease process.

Although blood cultures are not immediately useful in the acute diagnosis of meningitis, they may be of considerable clinical importance later in the management of the disease.

**Neuroimaging**

A cranial CT scan or magnetic resonance imaging (MRI) scan is indicated in the evaluation of any patient with a suspected CNS infection. Neuroimaging studies in acute meningitis are often normal, but approximately 50% may show abnormalities.

**BOX 99.3**

**Causes of Aseptic Meningitis**

### INFECTIOUS CAUSES

#### Viruses

- Enteroviruses—polio, Coxsackie, echovirus
- Herpes group of viruses
  - Herpes simplex virus (HSV) types 1 and 2
  - Varicella zoster virus
  - Cytomegalovirus
  - Epstein-Barr virus
  - Human herpes virus 6 (HHV-6)
- Respiratory viruses
  - Adenovirus
  - Rhino virus
  - Influenza virus types A and B
- Arboviruses
  - Mumps virus
  - Lymphocytic choriomeningitis
  - Human immunodeficiency virus (HIV)

#### Bacteria

- Partially treated meningitis
- Parameningeal infection
- Endocarditis
- *Mycoplasma pneumonia*
- *Mycobacterium tuberculosis*
- Ehrlichiosis
- *Borrelia burgdorferi*
- *Treponema pallidum*
- *Brucella*
- Leptospirosis

#### Fungi

- *Cryptococcus neoformans*
- *Histoplasma capsulatum*
- *Coccidioides immitis*
- *Blastomyces dermatitides*
- *Candida*

#### Parasites

- *Toxoplasma gondii*
- Neurocysticercosis
- Trichinosis
- *Naegleria*
- Hartmannella
- *Bartonella henselae*

#### Rickettsiae

- Rocky Mountain spotted fever
- Typhus

### NONINFECTIOUS CAUSES

#### Postinfectious/Postvaccinal

- Rubella
- Rubella

#### Drugs

- Nonsteroidal anti-inflammatory drugs (NSAIDs)
- Trimethoprim-sulfamethoxazole, amoxicillin
- Muromonab CD3 (OKT3)
- Azathioprine
- Intravenous (IV) immunoglobulin
- Isoniazid
- Intrathecal methotrexate
- Intrathecal cytosine arabinoside
- Allopurinol
- Carbamazepine
- Sulfasalazine

#### Systemic Disease

- Collagen vascular disorders
  - Systemic lupus erythematosus
  - Wegener’s granulomatosis
  - Central nervous system (CNS) vasculitis
  - Rheumatoid arthritis
  - Kawasaki’s disease
- Sarcoidosis
- Leptomeningeal cancer
- Post-transplantation lymphoproliferative disorder
- Behçet’s disease
- Vogt-Koyanagi syndrome

#### Neoplastic Disorders

- Leukemia
- Carcinomatous meningitis secondary to primary or secondary tumors of the brain

#### Inflammation of Neighboring Structures

- Brain abscess
- Epidural abscess

#### Miscellaneous

- Arachnoiditis
- Migraine
- Urinary tract infection

Cerebrospinal Spinal Fluid Analysis

CSF analysis is indicated whenever a CNS infection is suspected, unless the procedure is contraindicated by the presence of infection in the skin or soft tissues at the puncture site or the likelihood of brain herniation. In most patients with meningitis who have no focal neurologic findings (including no altered mental status), LP may be safely performed without antecedent neuroimaging studies. Because this may not be the case in other brain pathologies, in many circumstances we advise that a head CT be obtained before performing an LP. An algorithm for diagnostic and therapeutic decision making is presented in Figure 99.5. These indications should be carefully weighed against the patient's condition, the probability of meningitis, and the availability of the CT or MRI scan. In subtle cases, LP can create meningeal enhancement on a subsequent MRI. If viral encephalitis is suspected and treatment has already been initiated, we recommend performing the LP after the MRI.

Early initiation of antimicrobial therapy should not be delayed pending an LP. The algorithmic alternatives are: (1) immediate LP followed by initiation of antibiotic treatment before obtaining the results, or (2) initiation of antibiotic treatment followed by a head CT scan and then an LP. The latter choice of empirical treatment with antibiotics is now the routine in many institutions, although in some cases a third option could be considered: antibiotics and no LP despite an unremarkable CT scan.

The controversy emerging regarding not performing LP despite a lack of CT scan findings is based on some reviews and case reports describing herniation temporally related to LP in patients with normal CT scans. Raised ICP may not be reliably detected using CT. Clinical signs of increased ICP, rapid change in consciousness, and recent seizures have been identified as risk factors predicting deterioration despite a normal CT. The risks of ongoing
Cerebrospinal Spinal Fluid Collection

At least three sterile tubes each containing 1 to 1.5 mL of CSF are obtained and numbered in sequence. A fourth tube is desirable should later studies become necessary. The fluid is sent to the laboratory for immediate analysis of turbidity, xanthochromia, glucose, protein, cell count and differential diagnosis, Gram’s stain, bacterial culture, and antigen testing (Table 99.1). In certain cases, a cryptococcal antigen study (which is replacing the previously used India ink stain), a bacteriologic stain for acid-fast bacilli, or a Venereal Disease Research Laboratory (VDRL) test should be obtained. When only a small amount of fluid can be obtained, the most important studies are the cell count with differential diagnosis, Gram’s stain, and bacterial cultures. Ideally, the cell count should be performed on both the first and third or fourth tubes to help differentiate true CSF pleocytosis from contamination of the specimen by a traumatic LP.

The CSF is assessed immediately for turbidity or cloudiness by the person performing the LP. Normal CSF is completely clear and colorless and is indistinguishable from water, thus any degree of turbidity is pathologic. Leukocytosis is the most common cause
of CSF turbidity; counts greater than 200 cells/mm³ usually cause clinically detectable changes in CSF clarity.

**Cerebrospinal Spinal Fluid Cell Count**

Normal adult CSF contains no more than 5 leukocytes/mm³ with at most one granulocyte (polymorphonuclear [PMN] leukocyte); therefore, the presence of more than one PMN or a total cell count of more than 5 cells/mm³ is evidence of CNS infection. In addition, the presence of any eosinophil in the CSF is abnormal; occasionally basophils may be seen in the absence of disease. Pretreatment with a few doses of antibiotics, although possibly diminishing the yield of Gram's staining and cultures, should not affect the CSF cell counts in meningitis.

The cell counts in bacterial meningitis are usually markedly elevated, sometimes exceeding 10,000 cells/mm³, and demonstrate a dramatic granulocytic shift. In general, counts exceed 500 cells/mm³ with a preponderance of PMN leukocytes. However, the initial CSF analysis exhibits lymphocytosis (lymphocyte count greater than 50%) in 6% to 13% of cases of bacterial meningitis. When only the patients with bacterial meningitis with fewer than 1000 cells/mm³ are considered, 24% to 52% have a predominance of lymphocytes. In addition, the same population of patients often has only a mild disturbance of CSF glucose and protein levels. In well-established viral meningitis and encephalitis, counts are usually less than 500 cells/mm³ with nearly 100% of the cells being mononuclear. Early (48 hours) presentations may reveal significant PMN pleocytosis and hence be indistinguishable from presentations in early bacterial meningitis.

Similarly, normal cell counts and differential diagnoses, although reassuring, do not absolutely exclude bacterial meningitis. Patients who have a strong clinical suspicion for meningitis require hospitalization with frequent reevaluation, repeat LP, and antimicrobial therapy.

Brain abscess and parameningeal infections, such as subdural empyema or epidural abscess, usually display CSF cell counts and differential diagnoses similar to those of viral meningitis and encephalitis, although the CSF may also be normal.

A traumatic LP is suggested by the presence of a clot in one of the tubes or the clearing of the CSF and a decreasing red blood cell (RBC) count from tubes one to three. In the presence of a traumatic LP, one may estimate the true degree of CSF white blood cell (WBC) pleocytosis with the following formula:

\[
\text{True CSF WBC} = \frac{\text{(measured CSF WBC)} \times (\text{CSF RBC}) \times (\text{blood WBC})}{\text{blood RBC}}
\]

Alternatively, when peripheral cell counts are normal, the CSF from a traumatic LP should contain about 1 WBC per 700 RBCs.

**Gram’s Stain**

A properly performed Gram’s stain of a centrifuged specimen of CSF identifies the causative organism approximately 80% of the time in cases of bacterial meningitis. Gram’s stain characteristics of the most commonly encountered organisms are described in Table 99.2. The yield from this procedure is diminished by 20% to 30% when there has been prior treatment with antibiotics. Misidentification of gram-positive organisms as gram-negative is also known to occur more commonly among pretreated patients, because organisms with damaged walls stain unpredictably.

**Xanthochromia**

*Xanthochromia* is the yellowish discoloration of the supernatant of a centrifuged CSF specimen. It is abnormal and results from the lysis of RBCs and release of the breakdown pigments oxyhemoglobin, bilirubin, and methemoglobin into the CSF. This process normally begins within 2 hours, and pigments may persist up to 30 days; therefore early analysis of the LP specimen is essential. If a traumatic tap has introduced enough plasma to raise the CSF protein level to 150 mg/dL or more, blood pigments may cause xanthochromia. If the CSF protein level is less than 150 mg/dL, however, and systemic hypercarotenemia does not exist, xanthochromia of a centrifuged CSF specimen indicates that a SAH has occurred.

**Glucose**

When the serum glucose is normal, the CSF glucose is usually between 50 and 80 mg/dL. The CSF glucose is normally in a ratio...
of 0.6:1 to the serum glucose, except with marked systemic hyperglycemia in which case the ratio is closer to 0.4:1. Therefore, a CSF-to-serum glucose ratio of less than 0.5 in normoglycemic subjects or 0.3 in hyperglycemic subjects is abnormal and may represent the impaired glucose transport mechanisms and increased CNS glucose use associated with pyogenic meningitis. Mild decreases in the CSF glucose level may occur with certain viral and parameningeal processes. However, bacterial or fungal meningitis should be presumed to be the cause of low CSF glucose, termed hypoglycorrhachia, until each is clearly excluded. If the serum glucose level has increased rapidly (eg, after IV administration of 50% dextrose in water) equilibration in the CSF may take up to 4 hours, and therefore the interpretation of CSF-to-serum glucose ratios may be unreliable.

Protein

The normal CSF protein level in adults ranges from 15 to 45 mg/dL. An elevated CSF protein, usually higher than 150 mg/dL, commonly occurs with acute bacterial meningitis. When a traumatic LP has occurred, the CSF protein can be corrected for the presence of blood by subtracting 1 mg/dL of protein for each 1000 RBCs. Elevated CSF protein concentrations can result from any cause of meningitis, SAH, CNS vasculitis, syphilis, viral
and lactate may rise prior to the decline in glucose. Normal lactate levels (<2.8 mmol/L) are usually seen in patients with viral meningitides. A recent systematic review suggests that an elevated CSF lactate outperforms glucose, protein, and leukocyte count for diagnosing bacterial meningitis, but the strength of evidence is weak. At this time, we do not recommend using the CSF lactate as a definitive test, but it may have a role in the future.

C-reactive protein, CSF chloride, and the limulus lysate test do not have a defined utility in the evaluation of CNS infections.

**Antigen Detection**

Counterimmunoelectrophoresis (CIE), latex agglutination, and coagglutination are methods of detecting specific antigens and theoretically have value even in patients who have received antibiotics. However, no incremental yield of these methods have been theoretically shown to be superior to standard techniques of gram stain and culture. PCR has additionally been shown to be superior in identifying enteroviruses, and other viral etiologies in both immunocompromised and immuno-

**India Ink Preparation**

Historically, an India ink staining of the CSF was performed to diagnose cryptococcal meningitis. This has been replaced by cryptococcal antigen testing, which has a similar sensitivity when measured in serum, CSF, or urine.

**Lactic Acid and Other Markers**

Although nonspecific, elevations in CSF lactic acid concentrations (>2.8 mmol/L) are potentially indicative of bacterial meningitis, encephalitis, neoplasms, and demyelination syndromes. A greatly elevated CSF protein level (>1000 mg/dL) in the presence of a relatively benign clinical presentation suggests fungal disease.
nocompetent patients. PCR assays have nearly tripled the diagnostic accuracy when compared to viral cultures alone.

The growing availability of molecular techniques does not, however, suggest that they should be routinely employed as initial diagnostic tests. Most cases of acute bacterial meningitis are readily diagnosed and treated on the basis of the standard Gram stain and culture. PCR should be reserved for less clear presentations, patients pretreated with antibiotics, and cases in which concern exists for tuberculous, cryptococcal, and treatable viral CNS infections. A reasonable approach is to save the CSF and to consider ordering PCR when acute infection is strongly suspected based on the initial results from the cell count and Gram stain.

**Bacteriologic Cultures**

Although results are not available for emergency management, bacteriologic cultures of CSF should be performed. Bacterial culture yields are significantly decreased in patients pretreated with antibiotics. When suspicion for non-bacterial meningitis is high, viral cultures should also be considered. Although antigen testing holds promise, the low prevalence of these diseases and the lack of prospective studies have not established that antigen testing alone can replaced bacteriological cultures at this time.

**Additional Investigations**

As many as 50% of patients with pneumococcal meningitis also have evidence of pneumonia on an initial chest radiographic study. This association occurs in fewer than 10% of the cases of meningitis caused by Hib and N. meningitides, and in approximately 20% of cases of meningitis caused by other organisms. Approximately 10% of cases of brain abscess have an associated pulmonary infection on chest radiography, which may assist in identification of causative organisms and appropriate antimicrobial therapy.

**MANAGEMENT**

Initial management of the patient with a suspected CNS infection focuses on ensuring oxygenation and perfusion. Although there is concern regarding inducing brain edema with volume resuscitation, especially in children, establishing a mean arterial pressure that maintains cerebral perfusion takes priority. Acute cerebral edema or elevated ICP is managed with immediate endotracheal intubation and maintenance of eucapnia. Osmonic agents such as mannitol may be used while ensuring that the patient does not become volume depleted and hypotensive.

**Bacterial Meningitis**

Therapy for bacterial meningitis requires bactericidal antibiotics that penetrate the blood–brain barrier and achieve therapeutic CSF concentrations. Until the pathogenetic organism is identified, broad-spectrum coverage of the most common pathogens is indicated (Table 99.3). We recommend cefotaxime or ceftriaxone (2 grams IV in adults, 75 to 100 mg/kg in children, 50 mg/kg in infants younger than 1 month old), plus vancomycin (15 mg/kg) to cover potentially resistant organisms. High-dose ampicillin (100 mg/kg) is also added if concern exists about *Listeria*, *Propionibacterium acnes*, or *M. haemolyticum*.

**Other ancillary investigations** such as echocardiography, cultures of other body fluids, and bone scans may be undertaken as necessary to evaluate coexistent or complicated disease.

A number of characteristic but not pathognomonic electroencephalogram (EEG) abnormalities have been associated with HSV type 1 encephalitis. The presence of focal or lateralized EEG abnormalities in the presence of an encephalitis syndrome should be considered strong evidence supporting a diagnosis of HSV encephalitis; however, no literature exists to support emergent assessment of suspected meningitis or encephalitis with an EEG in the emergency department (ED).

<sup>a</sup>Ceftriaxone or cefotaxime.
<sup>b</sup>Some experts would add rifampin if dexamethasone is also given.

<sup>c</sup>In infants and children, vancomycin alone is reasonable unless Gram stains reveal the presence of gram-negative bacilli.

CSF, Cerebrospinal fluid.

particularly in elders and infants younger than 1 month old. In patients allergic to penicillin and cephalosporins, we recommend meropenem (2 grams IV) or chloramphenicol (12.5 mg/kg IV) plus vancomycin (15 mg/kg IV).

Corticosteroid treatment is additionally recommended in adult acute bacterial meningitis. However, the evidence of its efficacy is becoming less compelling over time as a result of the changing epidemiology in the developed world due to vaccines. Earlier resolution of the clinical and CSF stigmata of meningitis and a decrease in long-term hearing loss are observed in infants and children given dexamethasone with cefuroxime or ceftriaxone compared with those receiving the antibiotic alone, particularly when H. influenzae is the offending agent.

In adult bacterial meningitis, an absolute risk reduction of 10% for unfavorable outcome is seen when dexamethasone is given either 15 minutes before or concomitantly with antibiotics and continued for 4 days at 6-hour intervals. This benefit is greatest in those with S. pneumoniae. Despite uncertainty from conflicting trials, we recommend an initial dose of dexamethasone 10 mg IV prior to or concurrent with empirical antibiotics in patients with suspected community acquired meningitis and without signs of septic shock. Given the potential adverse effects of high dose corticosteroids in patients with septic shock, the use of low dose hydrocortisone at 50 mg IV instead of high dose dexamethasone is a reasonable approach, although clear benefit has not been demonstrated.

In pediatric meningitis, the evidence supporting adjunctive dexamethasone is even less compelling. Invasive Hib and pneumococcal infections have drastically been reduced by vaccination. A randomized trial of dexamethasone in childhood meningitis in sub-Saharan Africa did not demonstrate a benefit, and a retrospective analysis from United States data did not demonstrate a mortality benefit. Current recommendations are organism specific, which presents a major limitation, because recommendations are to begin empirical therapy prior to lab results in suspicious cases. Experts do not agree on a recommendation to use corticosteroids in pneumococcal meningitis, and data are not sufficient to demonstrate a clear benefit in children. Consequently, we do not recommend adjunctive dexamethasone at this time in the treatment of pediatric meningitis.

**Tuberculous Meningitis**

Early chemotherapeutic intervention in acute tuberculous meningitis improves the patient’s prognosis. A strong clinical suspicion of this disease is an adequate indication to begin antituberculous therapy. A standard treatment regimen consists of isoniazid, rifampin, pyrazinamide, and ethambutol or streptomycin. Corticosteroids have also been shown to decrease secondary complications.

**Fungal Meningitis**

Four agents are available to treat fungal meningitis: amphotericin B, flucytosine, miconazole, and fluconazole. Of these, amphotericin B, either alone or in combination with flucytosine, is the most commonly recommended initial therapeutic regimen. These diseases are rarely acutely life-threatening but rather are slowly progressive. Prolonged therapy, often with multiple agents, is necessary. The initiation of antifungal therapy is rarely indicated in the ED.

**Viral Meningitis**

No specific agents are available for treating most types of viral meningitis. Fortunately, with the exception of HSV meningitis, the viral meningitides contracted in the United States are generally characterized by a short, benign, self-limited course followed by a complete recovery. Therefore, the primary therapeutic consideration in cases of viral meningitis is the validity of the diagnosis. Early cases of viral meningitis may be indistinguishable from bacterial meningitis, and this confusion may not be resolved by CSF analysis; therefore, when any doubt exists about the veracity of the diagnosis, cultures should be obtained and the patient admitted to the hospital. Antimicrobial therapy for presumed bacterial meningitis may be initiated on the basis of the clinical presentation or may be withheld pending the outcome of close clinical observation and repeated LP in 8 to 12 hours.

**Viral Encephalitis**

When the diagnosis of herpes meningoencephalitis is suspected or established, IV acyclovir should be administered in a dose of 10 mg/kg every 8 hours. Ganciclovir, fosarnet, and cidovir are also effective in human herpes virus (HHV) infections, and plecanaril has been effective in enteroviral infections. Additional antiviral treatments are in development.

As many viral encephalitides are spread by mosquitoes or other insects, prevention by control of mosquito populations is an important method to limit the impact of West Nile virus and other insect-borne diseases. Insecticides appear to have a favorable benefit risk profile based on both ecological studies and statistical modeling.

**Central Nervous System Abscess**

The treatment of cerebral abscess requires neurosurgical consultation. The location, size, and number of abscesses influence the choice of medical management, surgical excision, aspiration, or a combination of these modalities. In general, small multiple abscesses are treated medically, whereas large, surgically accessible lesions should be excised. Empirical antimicrobial therapy before identification of specific organisms by aspiration or surgical excision should be guided by the principles of CSF penetration and the coverage of likely pathogens.

Otogenic and sinogenic abscesses are often treated with cefotaxime or ceftriaxone (75 to 100 mg/kg IV, usually 2 grams IV in adults) plus metronidazole. Abscesses with traumatic or neurosurgical origins should have antimicrobial coverage for S. aureus or methicillin-resistant S. aureus with vancomycin (15 mg/kg IV). Patients at high risk for tuberculous, fungal, or parasitic abscess should also receive coverage for the suspected etiologic agent. Corticosteroids should be reserved specifically for managing any attendant cerebral edema; in other circumstances, steroid use is associated with increased mortality.

**Chemoprophylaxis**

Among household contacts, the incidence of transmission of meningococcus is approximately 5%; therefore, we recommend that household contacts of bacteriologically confirmed cases receive rifampin (adults, 600 mg; children older than 1 month, 10 mg/kg; children younger than 1 month, 5 mg/kg) orally every 12 hours for a total of four doses. In addition, these contacts should be advised to watch for fever, sore throat, rash, or any symptoms of meningitis. They should be hospitalized with appropriate IV antimicrobial therapy if there are signs that active meningococcal disease is developing, because rifampin is ineffective against invasive meningococcal disease.

Intimate, non-household contacts who have had mucosal exposure to the patient’s oral secretions should also receive rifampin prophylaxis. Health care workers are not at increased risk for the disease and do not require prophylaxis unless they have had direct mucosal contact with the patient’s secretions, as
might occur during mouth-to-mouth resuscitation, endotracheal intubation, or nasotracheal suctioning. Ciprofloxacin 500 mg by mouth (adults only) and ceftriaxone 250 mg intramuscularly (125 mg intramuscularly for children younger than 15 years old) provide single-dose alternatives.

There is no indication for chemoprophylaxis in pneumococcal meningitis. Rifampin prophylaxis for the contacts of patients with Hib meningitis is recommended for nonpregnant household contacts when there are children younger than 4 years old in the household (adults, 600 mg by mouth; children, 20 mg/kg by mouth daily for 4 days).

**Immunoprophylaxis**

A quadrivalent vaccine based on the polysaccharide capsule and conferring protection against group A, C, Y, and W-135 meningococci has been in routine use by the United States military since the 1980s. However, the capsular polysaccharide vaccines used to immunize adults are neither immunogenic nor protective in children younger than 2 years old because of poor antibody response. In addition, no licensed vaccine is currently available against the serogroup B meningococcus. The serogroup B capsular polysaccharide has proved to be poorly immunogenic in both adults and children.

The vaccine is recommended in established meningococcal epidemics and for travelers to countries where meningococcal disease is currently epidemic. Elective vaccination of college freshmen has been recommended by the Advisory Committee on Immunization Practices (ACIP) in the United States and public health authorities in the United Kingdom. The United Kingdom has also implemented universal childhood immunization with a group C conjugate vaccine.

The development of effective pneumococcal vaccines has been hampered by the large number of serotypes of the organism. A single dose of the vaccine should be considered for elderly or debilitated patients, especially those with pulmonary disease, and for patients with impaired splenic function, splenectomy, or sickle cell anemia. A heptavalent conjugated pneumococcal vaccine has also been developed and is recommended for universal childhood immunization by the ACIP.

A conjugate vaccine effective against Hib has been developed for use in the pediatric, but not adult, population. It appears to be approximately 90% protective and has a very low incidence of adverse reactions. Modern childhood immunization against Hib has raised the average age of patients afflicted with Haemophilus meningitis to 25 years and decreased the incidence of meningitis of any etiology by 55%.

Vaccination is also available to confer immune protection against Japanese encephalitis virus, and it is recommended for people performing extensive outdoor activities or spending more than 30 days in endemic areas during transmission seasons. The reported protective efficacy of the vaccine is approximately 90%. Although there is no current human vaccine for the West Nile virus, vaccines for nonhuman mammals have been developed.

**DISPOSITION**

With the exception of viral meningitis, all but the most chronic CNS infections require initial inpatient evaluation and treatment. Bed rest, analgesics, and the institution of appropriate IV antimicrobials are indicated.

Some patients with suspected viral meningitides merit hospitalization. These include patients with more severe disease with refractory headache, immunocompromise, and suspicion of HSV meningitis. Although local practices vary, we recommend managing patients with classical presentations of viral meningitis as outpatients with close follow-up within 24 hours.

**KEY CONCEPTS**

- CNS infection should be considered in all patients with headache, neck stiffness, fever, altered sensorium, or diffuse or focal neurological findings.
- *S. pneumoniae* is one of the two leading causes of bacterial meningitis in adults. Mortality from *S. pneumoniae* is 30%.
- Perform (and document) a funduscopic examination and focused neurologic examination to include mental status (pay close attention to cranial nerves 2, 3, 4, and 6).
- Altered mental status in a patient with suspected meningitis can be a sign of increased ICP or encephalitis.
- Sampling of CSF is the only reliable method of assessing the presence or absence of meningitis. In the absence of contraindications, any suspicion of meningitis is an indication to perform a CSF analysis.
- Provide critical monitoring and be aware of the risk for rapid deterioration.
- Early initiation of empirical antimicrobial therapy is recommended in cases of suspected acute CNS infection. Antibiotic administration should not be delayed for CSF analysis or performance of neuroimaging studies.
- Antibiotic chemoprophylaxis should be assured for close contacts of patients with meningitis resulting from *N. meningitidis* or *H. influenza*. Single-dose and multiple-dose regimens are available.
- Concomitant CNS infection should be strongly considered in any symptomatic patient with another severe systemic infection, such as urinary tract infection or pneumonia.
- First line treatment for bacterial meningitis is ceftriaxone plus vancomycin.
- Acyclovir is recommended for patients with suspected meningoencephalitis.
- Dexamethasone is recommended prior to treatment with antibiotics in adults.
- Discuss with patients and families the critical nature of the disease and the potential for morbidity and mortality.

**CHAPTER 99: QUESTIONS & ANSWERS**

99.1. Which of the following is typically the first step in the pathogenesis of bacterial meningitis?
   A. Cutaneous colonization
   B. Direct invasion via a meningeal disruption
   C. Hematogenous seeding
   D. Middle ear colonization
   E. Nasopharyngeal colonization

**Answer:** E. Virulent microbes secrete proteases and induce cellular ciliostasis. They are then able to evade the complement pathway and cross the blood-brain barrier.

99.2. Which of the following is typically the first step in the pathogenesis of viral meninginitis?
   A. Cutaneous colonization
   B. Direct invasion via a meningeal disruption
   C. Hematogenous seeding
   D. Middle ear colonization
   E. Nasopharyngeal colonization

**Answer:** C. Viruses may enter the host through almost any portal, replicate outside of the central nervous system (CNS), and gain access via hematogenous spread.

99.3. In the pediatric population, where is the most common location of intraparenchymal brain abscesses that are otogenic in origin?
   A. Cerebellar
   B. Frontal
   C. Occipital
   D. Parietal I
   E. Temporal

**Answer:** A.

99.4. A 44-year-old woman presents with fever and headache of 2 days’ duration. Vital signs are remarkable for fever, tachycardia, and hypotension with a blood pressure of 80/40 mm Hg. Chest radiograph and noncontrasted computed tomography (CT) scan of the brain are unremarkable. Antibiotics are given. Laboratory evaluation is remarkable for leukocytosis with hemoglobin 12 g/dL, sodium 128 mEq/L, potassium 5.5 mEq/L, blood urea nitrogen (BUN) 25 mg/dL, creatinine 0.9 mg/dL, and bicarbonate 26 mEq/L. Lumbar puncture (LP) confirms meningitis with gram-negative cocci, pleocytosis, elevated protein, and low glucose. Opening pressure is 20 cm H₂O. Hypotension persists despite several liters of normal saline and titration of dopamine at 15 µg/kg/min. What should be the most appropriate next step?
   A. Hydrocortisone intravenously
   B. Mannitol 0.5 g/kg
   C. Norepinephrine
   D. Phentylephrine infusion
   E. Transfusion of packed red cells

**Answer:** A. Overall, the complications from meningococcal meningitis are less than with pneumococcal disease. The incidence of Waterhouse-Friderichen syndrome is dramatically higher. The presence of refractory hypotension, hyponatremia, and hyperkalemia strongly suggests adrenal insufficiency.

99.5. A 46-year-old man is brought to the emergency department (ED) for acute mental status changes and fever that have evolved rapidly over 24 hours. The emergency medical service (EMS) transport team reports a noticeable decline during transport. Immediately upon arrival, the patient experiences a brief grand mal seizure. Vital signs are temperature, 39.3°C; heart rate, 133 bpm; blood pressure, 110/60 mm Hg; respiratory rate, 20 breaths per minute; and oxygen saturation, 95%. Fluid resuscitation is begun. Noncontrast computed tomography (CT) scan of the head is negative. Physical examination is remarkable for modest meningismus. Which of the following statements is true?
   A. The next step should be blood cultures and antibiotics.
   B. The next step should be contrasted CT scan.
   C. The next step should be dexamethasone 10 mg intravenously.
   D. There are no predictable risk factors for herniation.
   E. Raised intracranial pressure (ICP) is reliably detected by CT scan.

**Answer:** A. The controversy regarding not performing a lumbar puncture (LP) despite a normal CT is based on emergency reports of a fulminant herniation syndrome temporarily related to LP preceded by a normal CT. These reports reinforce the fact that CT cannot exclude raised ICP. Risk factors for the herniation syndrome are clinical signs of raised ICP, acute mental
status deterioration, and recent seizures. In these cases, blood cultures and empirical antibiotics are indicated in lieu of a confirmatory LP.

99.6. Cerebrospinal fluid (CSF) turbidity is usually seen with CSF leukocytosis above which of the following?
   A. 100 cells/mm³
   B. 200 cells/mm³
   C. 300 cells/mm³
   D. 400 cells/mm³
   E. 500 cells/mm³

**Answer:** B. Leukocytosis is the most common cause of CSF turbidity.

99.7. Which of the following findings should be considered the cutoff for indicating a normal cerebrospinal fluid (CSF) result?
   A. Total cell count >4; polymorphonuclear (PMN) count = 0
   B. Total cell count >5; PMN count = 1
   C. Total cell count >6; PMN count = 2
   D. Total cell count >8; PMN count = 3
   E. Total cell count >10; PMN count = 4

**Answer:** B. Normal CSF contains at most five leukocytes with at most one PMN leukocyte.

99.8. A 27-year-old woman presents with fever, headache, and mild neck pain. Physical examination is unremarkable except for neck pain with mild meningismus and a fever of 39.5°C. Blood tests, chest radiograph, and urinalysis are negative. Lumbar puncture (LP) results are lymphocytes 3 cells/mm³ and polymorphonuclear (PMN) leukocyte is 0. Glucose and protein levels are normal. No organisms are seen on gram stain. What should be the next step?
   A. Computed tomography (CT) scan with intravenous (IV) contrast
   B. IV antibiotics and admission
   C. IV ceftriaxone and a 24-hour recheck
   D. Magnetic resonance imaging (MRI) scan
   E. Reassurance and analgesics

**Answer:** B. Normal cell counts and differential diagnoses, in the face of a compatible clinical picture, do not rule out meningitis. Such patients require antibiotics, admission, reevaluation, and sometimes repeat lumbar puncture (LP). Brain abscesses and parameningeal infections may likewise present with normal cerebrospinal fluid (CSF).

99.9. Cerebrospinal fluid (CSF) xanthochromia may persist for up to how long?
   A. 24 hours
   B. 2 days
   C. 7 days
   D. 14 days
   E. 1 month

**Answer:** E. CSF xanthochromia may persist for up to 1 month. Also, if a traumatic tap introduces enough protein to raise the CSF level to 150 mg/dL, blood pigments may cause xanthochromia.
Patients with a history of mental illness have a higher rate of emergency department (ED) visits than the general population. Patients with at least one primary psychiatric visit to an ED were over four times more likely to become frequent ED users compared to patients with none.¹ Psychiatric patients accounted for almost 10% of all ED visits in 2010.²

Patients are often brought to the ED by family, police, or emergency medical service (EMS) with concerning symptoms of disorganized thought or behavior. They may express language and ideas found to be inappropriate and disruptive to accepted patterns of social interaction. Whether the issue involves thought content (delusions) or thought form (structure of thinking), the clinical impression is that of psychosis (detachment from reality and societal norms). Acutely psychotic patients raise concerns of safety for themselves and those around them.

The emergency clinician’s role is to first prevent and control violent and disruptive behavior and then determine if the underlying etiology of the thought disorder is functional (psychiatric) versus organic (medical) in nature. Functional causes include schizophrenia and schizophrenia-like illness, mania or mood disorder–associated psychosis. Organic causes can mimic the psychotic behavior of functional psychosis. Medication effects, substance abuse, and certain medical disorders need to be excluded before psychosis can be attributed to an underlying psychiatric illness.

Schizophrenia often manifests as a thought disorder or psychosis. The prevalence of schizophrenia approaches 1% internationally. The incidence is approximately 1.5 new cases annually per 10,000 people. Slightly more men than women are diagnosed (1.4:1), and women tend to be diagnosed later in life.³ The mortality rate for schizophrenia is 2.5 times that of the general population and continues to grow. Migrants, urban dwellers, those with low social economic status, and those who live at higher latitude have an increased risk for the disease.

Although the etiology of schizophrenia is multifactorial, it has a substantial genetic component with 80% of the variation in the trait of the disease attributed to genetic factors.

Alterations in the dopaminergic, serotonergic, cholinergic, and glutamatergic dependent pathways have all been implicated in the pathophysiology of schizophrenia.⁴ Neuro-inflammation and white matter pathology may be associated with the disease. Neuropathological and neuroimaging studies provide consistent evidence of an association between schizophrenia and microglial activation and proliferation.⁵ Schizophrenia is also postulated to be related to environmental factors interacting with neurodevelopmental factors thereby increasing risk of the disease. Stress, perinatal hypoxia, poor nutrition, infections, vitamin D deficiency, and zinc deficiency have all been associated with the development of schizophrenia.⁶ Evidence supports the existence of a progressive continuum of psychotic illness, beginning with unipolar depression and progressing to bipolar disease, schizoaffective psychosis, and finally schizophrenia. Research has shown that primary cerebellar insults may occur early during brain development long before the illness is clinically expressed. Interactions between early neurodevelopmental disturbances and pathological events in postnatal brain maturation seem necessary to trigger the onset of overt schizophrenia.⁷

Thought disorders broadly affect mental activity and can be associated with varying degrees of functional impairment. The core psychopathology of schizophrenia and other thought disorders according to Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) includes hallucinations, delusions, disorganization, cognitive impairment, and negative symptoms.⁸ The positive symptoms of schizophrenia manifest in many forms, including distortion of reality. Hallucinations are the perception of a sensory process in the absence of an external source. They can be auditory, olfactory, visual, gustatory, or somatic in nature. The vast majority of people with schizophrenia experience auditory hallucinations.

Another impairment present in most schizophrenics is delusional thinking. Delusions are fixed, false beliefs that persist in the face of overwhelming contradictory evidence. Due to impaired insight, patients with thought disorders often have delusional explanations for their hallucinations. Delusions can be bizarre and clearly implausible, or they can be reasonable and understandable yet untrue.

Patients with schizophrenia typically display disorganization of behavior and thinking. Their use of disjointed speech patterns reflects their internal poor organization of thought. This results in a lack of a coherent focus of ideas. The most commonly observed abnormal speech patterns are tangentiality and circumstantiality where the narrative wanders away from the initial topic of conversation. More severe thought disorders include derailment, neologisms, word salad, and perseverations. In severe cases, there may be no understandable content and speech is utterly incomprehensible. A separate group of patients with a more extreme deficit in communication are those suffering from catatonia. This behavior includes immobility, stupor, mutism, resistance to instructions, oppositionalism, echo phenomena, and withdrawal. Although classically associated with schizophrenia because of the profound communication and thought deficiencies, more recent studies highlight a strong association of catatonia with mood and medical disorders. Despite their similar
Presentations, only a minority of catatonic patients suffer from schizophrenia.14

Along with disorganization, thought disorders can be associated with significant cognitive impairment. These difficulties with attention, memory, reasoning, verbal comprehension, and decision-making usually precede the onset of positive symptoms.11 These features are increasingly considered a core feature of thought disorders and not just the byproduct of other symptoms or medications.

Negative symptoms represent an absence or diminution of normal cerebral processes. Negative symptoms include blunted affect, emotional withdrawal, social withdrawal, poor rapport with other people, difficulty with abstract thinking, loss of spontaneous conversation, and stereotyped thinking. The negative symptoms of schizophrenia are associated with an insidious onset of disease, fewer remissions, and poorer long-term prognosis. They are also associated with worse premorbid interpersonal skills, lower intelligence quotient (IQ), and tend to progress over time.

The development of schizophrenia involves three phases. The premorbid phase is characterized by the development of negative symptoms with deterioration in personal, social, and intellectual functioning. The patients are often young and may progressively withdraw from social actions. They may neglect personal appearance and hygiene. They experience deterioration of work, school, and home life. The progressive phase is often precipitated by a stressful event with the development of positive symptoms. The progressive phase can be said to begin when the patient develops the classical characteristics of schizophrenia mentioned earlier. Patients can become agitated or exhibit a hypervigilant withdrawal state characterized by rocking or staring and the patient may be violent and acting bizarrely. It is during the progressive phase that the patient is most likely to be brought to the ED by family, friends, police, or concerned bystanders. The residual phase is characterized by persistence of residual symptoms and disability. Impaired social and cognitive ability, poor hygiene, delusions, bizarre behavior, and social isolation can occur. On average, functional outcome is poor and patients may have varying levels of treatment resistance. Mortality is substantially increased due to elevated suicide risk and increased rates of poorly controlled medical comorbidities.

**DIFFERENTIAL DIAGNOSIS**

**Medical Disorders**

Numerous acute and chronic medical conditions can precipitate thought disorders (Box 100.1). Additionally, patients with underlying psychiatric disease may develop medical disorders that can exacerbate behavioral symptoms and cloud the distinction between psychiatric and organic brain disease.

Factors associated with primary medical conditions include new onset of symptoms, acute change in mental status, recent fluctuation in behavioral symptoms, onset in fifth decade of life or older, onset of symptoms after the patient has already been admitted to a medical care setting, and the presence of nonauditory hallucinations, lethargy, abnormal vital signs, and poor performance on cognitive function testing, particularly orientation to time, place, and person. Primary psychiatric conditions are more commonly associated with auditory hallucinations, a family history of psychosis, and an insidious onset in the late teens to mid-twenties. Medical delirium is common in elders; therefore, special attention should be paid to symptoms of psychosis in this population. Health care providers frequently ascribe medical delirium to other causes, such as dementia, psychosis, or depression.12 Medical delirium can be frequently missed in elders brought to the ED for alterations in behavior.13

**Box 100.1**

**Medical Disorders That May Cause Acute Psychosis**

**METABOLIC DISORDERS**
- Hypercalcemia
- Hypercarbia
- Hypoglycemia
- Hyponatremia
- Hypoxia

**INFLAMMATORY DISORDERS**
- Sarcoidosis
- Systemic lupus erythematosus
- Temporal (giant cell) arteritis

**ORGAN FAILURE**
- Hepatic encephalopathy
- Uremia

**NEUROLOGIC DISORDERS**
- Alzheimer’s disease
- Cerebrovascular disease
- Encephalitis (including HIV infection)
- Encephalopathies
- Epilepsy
- Huntington’s disease
- Multiple sclerosis
- Neoplasms
- Normal-pressure hydrocephalus
- Parkinson’s disease
- Pick’s disease
- Wilson’s disease

**ENDOCRINE DISORDERS**
- Addison’s disease
- Cushing’s disease
- Panhypopituitarism
- Parathyroid disease
- Postpartum psychosis
- Recurrent menstrual psychosis
- Sydenham’s chorea
- Thyroid disease

**DEFICIENCY STATES**
- Niacin
- Thiamine
- Vitamin B12, and folate

*HIV: Human immunodeficiency virus.*

Patients intoxicated with drugs of abuse are often brought to the ED because of bizarre or dangerous behavior. Street drugs such as cocaine, amphetamines, bath salts, hallucinogens, and synthetic cannabis affect the serotonergic and dopaminergic pathways and can provoke psychotic reactions resembling a primary psychotic disease or can disclose latent schizophrenia.14 Certain pharmacologic agents may also cause acute psychosis and mimic a thought disorder (Box 100.2).

**Psychiatric Disorders**

Once medical causes have been ruled out and the etiology is believed to be psychiatric, it can be helpful to classify which type of psychosis the patient is experiencing. The DSM-5 uses four classes of information to distinguish among the various types of
psychosis: type of psychotic symptom, course of illness, consequences of illness, and exclusions. Each category can help distinguish schizophrenia from other disorders that include psychosis among their symptoms. The DSM-5 definition of schizophrenia is included in Box 100.3.

A brief psychotic disorder involves the sudden onset of psychotic symptoms in response to major stress and lasts from several days up to 1 month. Peripartum psychosis is included under the diagnosis of brief psychotic disorder. Patients with schizophreniform disorder have similar symptoms to a brief psychotic disorder and last from longer than 1 month to less than 6 months. Up to one-third of patients with schizophreniform disorder can recover within 6 months; the other two-thirds develop clinical schizophrenia. Patients with mood disorders may develop psychotic symptoms as part of their disease. If psychotic symptoms develop during periods of mood disturbances, the diagnosis of mood disorder with psychotic features applies. If symptoms consistent with schizophrenia persist for more than 2 weeks in the absence of prominent mood episode, the diagnosis of schizoaffective disorder is made. Patients with personality disorders may occasionally develop brief psychotic episodes especially under stress. None of the aforementioned disturbances can be attributable to the effects of a substance or another medical condition.

Delusional disorder is characterized by one or more delusions that are present for longer than 1 month and the criteria for schizophrenia have not been met. Patients may believe famous
Diagnoses are contributing to the symptoms of psychosis. Risk factors for violence in patients with schizophrenia include gross excitement, prior violence, auditory hallucinations, systematization of delusions, incoherence of speech, and long duration of illness. In contrast, traits such as substance abuse and antisocial episodes are not recognized as significant violence-associated factors. Strategies to control disruptive and violent behavior in psychosis and thought disorders include de-escalation techniques, chemical sedation, and physical restraints. Although chemical and physical intervention can be appropriate when patients are demonstrating dangerous behavior, non-physical intervention, such as verbal de-escalation should be considered first. The clinician should demonstrate a calm, non-judgmental demeanor while showing appropriate concern and avoiding excessive stimulation, posturing, and prolonged eye contact. The patient should be given an opportunity to express their concerns, as well as identify unmet needs that can be easily corrected (eg, inadequate pain control, communication failures, or social concerns). If available, consider recruiting trusted others (eg, family, friends, case managers) to help prevent further agitation.

When verbal de-escalation is ineffective or inappropriate, physical restraint or use of seclusion may be necessary. Risk factors for the use of restraint or seclusion include referrals initiated by a third party, patients arriving to the ED in restraints, and clinician perception of the patient as severely disruptive, already exhibiting psychosis, or experiencing a manic episode.

Chemical restraint for psychomotor agitation is a common and necessary intervention. Speed of onset and reliability of delivery are two important factors to consider when selecting a route of administration of sedation in the behaviorally disturbed patient. Oral sedation is indicated when the patient can be safely verbally de-escalated, is not at imminent risk of harm to self, and agrees to take oral medications. When more expedient sedation is required, parenteral route has the advantages of immediate effect and titration of dosing. The goal of titration in this setting is the induction of rousable sleep, not unconsciousness.

Benzodiazepines and antipsychotics are the two medications most commonly used for chemical restraint. Using a single agent or, for more disturbed patients, a combination of the two classes, can be considered. Common agents and dosages are listed in Table 100.1.

Combined with concurrent physical restraint and the risk of previously ingested intoxicants, there is significant risk for oversedation and respiratory compromise. The combination of haloperidol and lorazepam causes respiratory depression in up to 50% of patients with a significant number also experiencing a hypoxic event. Fortunately, most episodes are quickly corrected with verbal stimulation or airway repositioning. As a result, we recommend the use of pulse oximetry or CO2 monitoring in chemically restrained patients to detect early signs of respiratory

thought disorders. In addition to monitoring of airway and level of consciousness, sedated and restrained patients should have frequent behavioral monitoring. The use of physical restraints may cause excess pressure on the patient’s neck, chest or abdomen, and requires ongoing direct visualization. Potentially hazardous articles and possessions should be removed from the patient’s area. Restrained patients are known to forcibly remove Foley catheters without deflation of the balloon if their limbs are released prior to removal of the catheter, resulting in urethral injury.

A detailed discussion of the use of physical and chemical restraints is provided in Chapter 189.

**DISPOSITION**

Making an appropriate disposition for patients with decompensated thought disorders is often difficult in today’s emergency medicine practice environment. Although institutional and community psychiatric resources vary widely by region, there appears to be a nationwide trend of diminishing psychiatric referral resources in the presence of rising numbers of psychiatric-related ED visits. The number of inpatient psychiatric beds nationwide has decreased dramatically, and many EDs “board” psychiatric patients for extended periods of time.

Appropriate disposition is based on the etiology of the underlying psychosis, response to treatment, consideration of patient and community safety, and an appropriate outpatient follow-up plan.

Patients who are actively suicidal, dangerous to others, possess severe mental debilitation precluding self-care, or are having their first psychotic episode should be admitted. The decision for inpatient psychiatric admission is not always precise. There may be disagreement between emergency clinicians and consulting psychiatrists regarding need for involuntary hold and final disposition, but psychiatric consultation can help confirm safety for discharge, help facilitate inpatient admission, and aid in outpatient follow-up.

Telemedicine is emerging as a technology that may ease the growing lack of adequate psychiatric resources for ED patients by facilitating urgent psychiatric consultation. A recent study demonstrated that telemedicine can be used safely and is not associated with significant differences in care when compared with face-to-face psychiatric evaluations.

Medication noncompliance is a common reason for a known schizophrenic to present to the ED with a decompensated psychotic episode. A patient whose psychosis stabilizes in the ED with medication can sometimes be safely discharged back into the community. Safe discharge planning can be accomplished provided that the patient has adequate ability to care for self and does not pose a risk of harm to self or others. Insight by the patient and judgment to adhere to an agreed course of action, including taking medication, is typically required. Patients with severe underlying psychiatric illnesses may have some degree of persistent mental disability even when optimally treated. For these patients, recruiting family or friends familiar with the patient can help establish that the patient is back to his or her baseline to ensure safety. A safe transition to the community setting requires adequate social support, including follow-up with a mental health service.

**KEY CONCEPTS**

- Thought disorder symptoms can be precipitated by psychiatric, underlying medical, and toxicologic etiologies.
- Diagnostic testing should be patient specific and based on the particular medical processes that the clinician feels may be causing or exacerbating the thought disorder, rather than panels of routine tests.
- Consider nonphysical intervention first when appropriate, but chemical sedation and physical restraint are immediately necessary for patients who demonstrate aggressive and dangerous behavior.
- Appropriate disposition depends on the etiology of the underlying psychosis, response to treatment, and patient and community safety considerations and, more often than not, includes psychiatric consultation.

CHAPTER 100: QUESTIONS & ANSWERS

100.1. Which of the following pharmacologic agents have been implicated in causing acute psychosis? 
A. Aripiprazole, hydralazine, nitroglycerin 
B. Diazepam, rifampin, captopril 
C. Hydrochlorothiazide, acetaminophen, albuterol 
D. Lorazepam, salasate, rocuronium 
E. Penicillin, ceftriaxone, risperidone

**Answer:** B. Box 100.2 provides an extensive list of other agents that may cause psychosis.

100.2. Rapid tranquilization using a neuroleptic agent would be indicated in which of the following cases? 
A. An intoxicated schizophrenic 
B. Anticholinergic psychosis 
C. A lactating schizophrenic 
D. A phencyclidine overdose 
E. A pregnant schizophrenic

**Answer:** A. Neuroleptics are contraindicated in choices B to E. They should not be the sole agent for alcohol withdrawal but would be useful for acute psychotic agitation.

100.3. A 45-year-old woman presents to the emergency department (ED) for a complaint of severe anxiety and unrest. Her past history is significant only for moderate schizophrenia, for which she was placed on olanzapine 2 months prior. She has been compliant. Physical examination is remarkable for the presence of anxiety, clear sensorium and orientation, and normal speech. She is restless pacing the room and reports being compelled to keep moving. Urine drug screen is negative. What would be the most appropriate therapy? 
A. Benztpirine orally 
B. Lorazepam orally 
C. Olanzapine intravenously 
D. Psychiatry consultation 
E. Ziprasidon intravenously

**Answer:** A. Akathisia is a state of motor restlessness characterized by a physical need to be constantly moving. The patient does not want to do so but feels compelled. It is most commonly seen in middle-aged patients within the first few months of starting treatment. It may be mistaken for an acute deterioration, but psychotic features are not increased. Treatment is with oral beta-blockers and anticholinergics (benztpirone).

100.4. What is the most common adverse effect seen with neuroleptic agents? 
A. Akinesia 
B. Dystonia 
C. Orthostatic hypotension 
D. Pseudoparkinsonism 
E. Tardive dyskinesia

**Answer:** B. Dystonia occurs in 1% to 5% of this patient population. The reaction occurs because of a dopaminergic pathway disruption with a resulting cholinergic predominance. Anticholinergics should be administered parenterally (Benadryl 25 to 50 mg intravenous [IV] or Cogentin 1 or 2 mg IV), followed by 48 to 72 hours of oral follow-up treatment to prevent recurrence. Patients may experience tongue protrusion (buccolingual crisis), upward eye deviation (oculogyric crisis), back arching (opisthotonus), and, rarely, laryngospasm. Symptoms may lessen with voluntary muscle action and increase with stress.

100.5. A 27-year-old known schizophrenic is brought to the emergency department (ED) for altered mental status. He started 4 weeks ago with subsequent dose increases. He has no other past history. Physical examination is remarkable for a muscular black man who is somnolent and diaphoretic. He withdraws all extremities stiffly and delirium in older emergency department patients. Acad Emerg Med 21(8):937–940, 2014.

minute. Rectal examination is guaiac positive. Foley placement shows brown urine. What should be the next diagnostic maneuver?
A. Creatine kinase level
B. Head computed tomography (CT) scan
C. Lumbar puncture
D. Thyroid hormone levels
E. Urine drug screen

**Answer:** A. Neuroleptic malignant syndrome is an idiopathic condition clinically similar to serotonin syndrome and malignant hyperthermia. Milder cases may be confused with serotonin syndrome. Severe cases, related to possible hypothalamic dysfunction, present with fever, rigidity, altered mental status, autonomic instability, and elevated creatine phosphokinase (CPK) and possibly rhabdomyolysis. It is seen with both typical and atypical antipsychotics and generally occurs in the first few weeks of treatment. Complications may include hepatic/renal failure, gastrointestinal (GI) hemorrhage, and respiratory failure. Severe cases may require intravenous dantrolene or dopamine agonists (eg, bromocriptine).
Mood Disorders
Leslie S. Zun | Kimberly Nordstrom

**PRINCIPLES**

Mood is a subjective emotional state. It is normal human experience to have fluctuations in mood in response to occurrences in everyday life. A change in mood becomes a “mood disorder” when it significantly impairs functioning. In the emergency department (ED), patients with mood disorders often present grossly debilitated, with thoughts of suicide, homicide, or profound self-neglect. These patients frequently present in emotional crisis, but this may not be their presenting complaint. Approximately, one-fourth to one-third of ED patients screen positive for mood disorders.

The Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5), divides mood disorders into two broad categories: depressive disorders and bipolar disorders. Mood disorders may also be due to a general medical condition or substance-induced mood disorders. Because the specific pathophysiologic mechanisms of these disorders are not fully understood, they are categorized by groupings of symptoms that persist for defined lengths of time.

**EPIEMIOLOGY**

Mental health patients are the fastest growing group of patients presenting to the ED. In 2007, 13% of the 94 million ED visits in the United States were for psychiatric reasons, which was an increase from 5% in 2000. This increase is nearly double what would have been expected by population growth alone. Up to 50% of Americans will meet the criteria for a DSM-5 disorder sometime in their life, with an estimated 21% having a mood disorder.

The World Health Organization (WHO) ranks major depressive disorder as one of the most prevalent and disabling diseases in the world. The 12-month prevalence for major depressive disorder is 5% and the lifetime prevalence is 13%. Patients with major depressive disorder frequently have other comorbid mental health issues, including anxiety disorders, personality disorders, and substance use disorders.

The lifetime prevalence of bipolar spectrum disorders is approximately 4%. Both severe depression and mania are serious and potentially life-threatening. Up to 80% of patients with bipolar disorder will exhibit suicidal behavior, and half will attempt suicide. Suicidal behavior can occur during all phases of bipolar disorder, but patients experiencing a depressed or a mixed episode are at higher risk, especially those with severe depressive symptoms and a sense of hopelessness.

**PATHOPHYSIOLOGY**

The pathophysiology of the mood disorders is not well established, but much is known about the neurophysiology, genetics, and psychosocial aspects of the disorders.

**Neurophysiology**

Antidepressants work by increasing the availability and activity of serotonin and norepinephrine at the synapse to stimulate the postsynaptic neuron. This is done by direct binding to the presynaptic and postsynaptic receptors, blocking reuptake of the neurotransmitter or inhibiting the enzymatic breakdown of the neurotransmitter. Because norepinephrine and serotonin systems traverse large portions of the brain, monoamine deficiency is hypothesized as a cause of depression. Depletion of oral tryptophan and tyrosine, amino acids essential for the production of serotonin and norepinephrine, respectively, can induce a depressive episode in subjects with a history of depression but not in healthy controls. Monoamine metabolite levels in cerebrospinal fluid, plasma, urine, and postmortem brains of patients with depression have not been reliably found to be deficient, indicating that there could be downstream effects involving second-messenger systems, such as cyclic adenosine monophosphate and phosphatidylinositol.

Other neurotransmitter systems may play a role in the development of depression. Decreased levels of both glutamate and γ-aminobutyric acid have been found in the prefrontal cortex of depressed subjects. Intravenous ketamine, an N-methyl-D-aspartate (NMDA) antagonist, induces a rapid antidepressant effect and suggests a role for glutamate in the pathophysiologic process of depression. The brain relies on the actions of protective and regenerative cytokines, such as brain-derived neurotrophic factor (BDNF). All known antidepressants raise levels of BDNF and subsequently result in neurogenesis of certain brain regions, such as the hippocampus. Other theories include the melatonergic system and related abnormalities in circadian rhythm, decreased neurosteroid synthesis, impaired endogenous opioid functioning, monoamine-acetylcholine imbalance, inflammatory effects of cytokines, and dysfunction of specific brain structures and circuits.

The neurophysiology of bipolar disorder is less well understood than unipolar depression, in part because of the fluctuating mood states and the heterogeneity of the disorder. Bipolar disorder may in part arise from abnormalities in the connections within and between structures in the brain. Specifically implicated are circuits interconnecting the amygdala, hypothalamus, striatum, and subdivisions of the frontal cortex, all of which are involved in both the generation and regulation of emotion.

**Neuroanatomy**

Neuroimaging studies of the brain suggest that abnormalities in certain areas and the interconnections between those areas may be involved mood disorders. A common magnetic resonance imaging (MRI) finding in patients with mood disorders, especially bipolar disorder, is an increased occurrence of subcortical hyper-intensities in the periventricular areas, basal ganglia, and thalamus. High-resolution MRI demonstrates reduced volumes in the hippocampus, orbital cortex, and anterior cingulate. These findings are associated with more severe illness, bipolar disorder, and increased cortisol levels. Volume reduction in the hippocampus is associated with high illness chronicity.

The amygdala is a clustering of nuclei that process emotional stimuli, especially fear, anger, and sadness. Functional neuroimaging suggests that amygdala activity is increased when the subject...
is exposed to emotionally relevant stimuli. The amygdala has connections throughout the brain. A decreased amygdala volume has been associated with unipolar depression.

**Endocrine System**

Physiologic changes such as increased alertness, decreased appetite, increased heart rate, and activation of the hypothalamic-pituitary-adrenal (HPA) axis occur when a person is stressed. The HPA axis may play a role in depression, especially in cases of early childhood and chronic stress. Activation of the HPA axis releases corticotropin-releasing hormone (CRH) from the hypothalamus. Although not specific, patients with depression may have increased levels of free cortisol in the plasma, cerebrospinal fluid, and urine. Increased CRH has been demonstrated in cerebrospinal fluid, and increased levels of CRH messenger RNA and protein have been demonstrated in limbic brain regions. Although none of these measures is reliable as a diagnostic tool, successful treatment to remission has been shown to reverse some of these abnormalities.

**Genetics**

Genetic vulnerability to mood disorders has not been traced to a single gene. It is likely to be due to the additive effects of many genes and environmental influences on how these genes are expressed. Family, twin, and adoption studies provide evidence that major depressive disorder is a familial disorder but is less heritable than bipolar disorder. Bipolar disorder is one of the most heritable medical illnesses with a heritability of 80% to 85% and a monozygotic twin concordance of about 40%.

**Psychosocial Factors**

The etiology of most psychiatric problems, including mood disorders, involves complex interactions between both biologic and psychosocial factors. The complex neural mechanism that regulates mood responds to and is modified by each person’s experience, including events in early childhood, such as childhood sexual abuse, reward and punishment during growth and development, other lifetime trauma, marital problems, low social support, and various kinds of loss. Psychosocial theories of mood disorder form the basis for psychotherapy.1

**CLINICAL FEATURES**

**Major Depressive Disorder**

Major depressive disorder is characterized by one or more major depressive episodes, as defined by DSM-5 criteria (Boxes 101.1 and 101.2). A major depressive episode is characterized by disturbances in four major areas: mood, psychomotor activity, cognition, and vegetative function. The patient must have at least five symptoms for a minimum of 2 weeks and one of the five must be depressed mood or anhedonia (decreased interest or pleasure).3

**Mood Disturbances**

Patients in a depressed state often feel profoundly hopeless and helpless. There are many words and phrases that can be used to describe feeling depressed; some patients will not recognize that they are “depressed” but rather they may describe the feeling in some other manner. Someone feeling no emotion (profoundly depressed) may answer “no” when asked about depressed mood.

On the other hand, a person may meet criteria for a major depressive episode and not be experiencing a depressed mood. Depression can also be manifested as a decreased capacity to experience pleasure or interest in otherwise pleasurable activities. This loss of interest is known as *anhedonia*.

As noted previously, the patient must exhibit a depressed mood or anhedonia to meet DSM-5 criteria for a diagnosis of a major depressive episode.1

---

**BOX 101.1**

**Summary of Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Criteria for a Major Depressive Episode**

A. Five or more of the following symptoms have been present almost every day during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure. Note: Do not include symptoms caused by a general medical condition.

1. Depressed mood (can be irritable mood in children and adolescents)
2. Loss of interest or pleasure in activities
3. Significant weight loss when not dieting or weight gain, or decrease or increase in appetite
4. Insomnia or hypersomnia
5. Psychomotor agitation or retardation
6. Fatigue or loss of energy
7. Feelings of worthlessness, or excessive or inappropriate guilt
8. Diminished ability to think or concentrate, or indecisiveness
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation, or a suicide plan or attempt

B. Symptoms cause clinically significant distress or impairment in social, occupational, or other functioning.

C. Symptoms are not caused by direct physiologic effects of a substance (eg, drug of abuse, medication) or a general medical condition (eg, hypothyroidism).

D. Symptoms are not better explained by another mental health disorder.

E. There has never been a manic or hypomanic episode.

**BOX 101.2**

**Mnemonics for the Symptoms of Depression and Mania**

**MNEMONIC FOR THE SYMPTOMS OF DEPRESSION**

| Irritability |
| Grandiosity |
| Flight of ideas |
| Activity increased |
| Sleeplessness |
| Thoughtlessness (impulsivity, increased risk taking) |
Disturbances in Psychomotor Activity

Physical activity in depression can be either increased or decreased. Psychomotor retardation is a significant slowing of physical activity. When suffering from psychomotor retardation, thinking and speaking can be slow, causing delayed responses to answers. Depressed patients often describe feeling fatigued with a general lack of energy and motivation. Conversely, patients may display psychomotor agitation, which can be manifested as fidgeting, pacing, hand wringing, or restlessness.

Vegetative Disturbances

Vegetative symptoms include disturbances in three major areas: sleep, appetite, and sexual function. Depressed patients may complain of insomnia or hypersomnia. Insomnia may be manifested as difficulty in falling asleep, frequent awakenings throughout the night, or early-morning wakening. Depressed patients with hypersomnia may report sleeping 12 to 14 hours or more a day. Alterations in appetite and eating patterns can also occur, resulting in significant weight gain or loss during a short time. Loss of interest in sexual activity and impaired sexual functioning may also accompany depression, although this is not listed as a DSM-5 criterion.

Thought Process and Content

Depressed patients often describe impaired concentration and forgetfulness. Executive functioning can also be impaired. In severe cases, this results in a decreased ability to perform basic activities of daily living.

Thought content tends to be negatively biased, such as recurrent thoughts of guilt, failure, worthlessness, and self-criticism. Patients in a depressed episode are at increased risk for suicide. Suicidal thoughts may range from vague notions that life is not worth living (passive) to fully envisioned suicide plans with definitive intent to kill themselves (active). All depressed patients must be questioned about suicidal thoughts. Because patients are not often forthcoming with their thoughts on suicide, a thorough review of risk factors and protective factors needs to form the basis of clinical decisions for providing the necessary level of care.

Patients with severe depression may have psychotic symptoms. The hallucinations and delusions that accompany depression are usually mood congruent, meaning that the themes of the psychotic content are consistent with the depressed mood.

Masked Depression

Mood disorders may not be clear at presentation. The depressed patient may have only vague somatic symptoms. Common complaints include weakness, fatigue, headache, and abdominal pain with medical evaluations occurring in response. Patients may not be aware of their depression and are often heavy users of medical care. Over half of patients with major depressive disorder initially present with somatic symptoms only which can mask a hidden depression. Clues that suggest a mood disturbance include the recent onset of a set of unusual behaviors, significant social disturbance, such as job loss, financial stress and marital difficulties, and self-destructive behavior (e.g., substance abuse, sexual promiscuity).

Special Considerations

Children and Adolescents. Criteria for depression in children and adolescents are the same as for depression in adults. Depression in these age groups can, however, present differently.

Prepubertal children are more likely to have somatic complaints, psychomotor agitation, and mood-congruent hallucinations and less likely to have disturbances in sleep and appetite. Some children are misdiagnosed as having attention deficit disorder, especially if symptoms involve poor concentration, listlessness, agitation, and withdrawal from daily activities.

Adolescents with depression may show increased irritability, oppositional behavior, and substance abuse. Other characteristics are social withdrawal, increased rejection sensitivity, and decline in school performance. Some adolescents may be first diagnosed with depression on receiving treatment for drug and alcohol problems.

Disruptive Mood Dysregulation Disorder. A newly described phenomenon for children who may have been previously diagnosed with depression or bipolar disorder is disruptive mood dysregulation disorder. Children and adolescents given this diagnosis display severe, recurrent outbursts that are out of proportion for the situation and are inconsistent with developmental level. The outbursts must occur three or more times a week, and the mood in between outbursts is irritable or angry most days. There are duration criteria of 12 months with no periods of three or more consecutive months not meeting criteria. Symptoms must occur prior to age 10.

Geriatric Patients. Depression is more common in elders because of more frequent occurrences of loss, comorbid health issues, and loss of autonomy. The elderly have a tendency to report more somatic complaints when depressed. They are also more vulnerable to development of melancholic depression, which is characterized by early morning awakening, diurnal variation in mood, low self-esteem, and low mood reactivity. Older depressed patients can also present with symptoms involving memory loss, inattention, withdrawal from daily activities, and lapses in personal and social hygiene that suggest dementia rather than depression. When such symptoms are from depression, the condition is called pseudodementia. Serious depression in elders is a highly treatable, reversible condition.

Other Depressive Disorders

Postpartum Depression

Postpartum depression is a depressive disorder that occurs during or within 4 weeks of delivery and would allow for the specifier “with peripartum onset.” Symptoms of depression are common in the perinatal period. As noted in the DSM-5, between 3% and 6% of women will experience the onset of major depression during pregnancy or within the following weeks to months. Similarly, but less severe, up to 65% of mothers report some depressed mood after childbirth, often called postpartum blues. Symptoms are generally mild and transient; although in 10% of mothers, it may lead to a full-fledged episode of major depression.

Postpartum mood episodes with psychotic features can be particularly dangerous. Infanticide is most often associated with command hallucinations to kill the infant or associated delusions. The risk for this is most closely related to a past history of postpartum episodes with psychosis, a history of depression or bipolar disorder, or a family history of bipolar disorder.

Persistent Depressive Disorder

Persistent depressive disorder is a new diagnosis that combines two former diagnoses: chronic major depressive disorder and dysthymic disorder. Specific criteria include the following: depressed mood most of the day, most days for at least 2 years;
two or more of the following: poor appetite or overeating, insomnia or hypersomnia, low energy or fatigue, low self-esteem, poor concentration or difficulty making decisions, and feelings of hopelessness; never more than 2 months of the 2 years without symptoms; and must cause significant distress or impairment in functioning. Exclusion criteria include a history of hypomania or mania and a history of psychotic illness. Also, it cannot be due to a substance or medical condition. There are multiple specifiers that can be applied to this diagnosis.

Premenstrual Dysphoric Disorder

Premenstrual dysphoric syndrome is a new diagnosis included in the DSM-5. At least five of the listed symptoms must be present in the final week before the onset of menses and start to improve within a few days after the onset of menses and be absent or minimal in the week post menses. These symptoms must be present for most cycles over the preceding year. The onset can occur at any point after menarche. Risks for development include stress, history of interpersonal trauma, seasonal changes, and sociocultural aspects of female sexual behavior.

Seasonal Affective Disorder

Seasonal affective disorder is not a separate mood disorder, but rather, a specifier of major depressive disorder. An example of the use of a specifier is “major depressive disorder, recurrent, moderate, with seasonal pattern.” This specifier can only be used with a recurrent major depressive disorder. The criteria for this include the following: a regular temporal relationship between onset of depressive episode and a particular time of year, full remissions at a specific time of year, two depressive episodes within 2 years that demonstrate a temporal relationship, no nonseasonal episodes within the same period, and substantially more seasonal depressive episodes than nonseasonal episodes over the person’s lifetime. Melatonin, a hormone secreted in the brain and produced at high levels in the dark, has been implicated in the etiology of this disorder. Phototherapy is an effective and safe treatment of seasonal depression. Light exposure to the eyes seems to be essential, but the exact mechanism of action is still unknown.

Bipolar Disorders

Bipolar disorder is lifelong, with episodic exacerbation of symptoms and deterioration of function characterized by extreme mood episodes. Patients with bipolar disorder may require different forms and intensities of treatment at different stages of the illness. Bipolar I disorder includes at least one manic episode, and patients have typically had one or more major depressive episodes, although a depressive episode is not necessary for diagnosis. Bipolar II disorder involves a hypomanic episode and at least one major depressive episode. A hypomanic episode includes the features of a manic episode without psychosis, marked impairment of function, or the need for hospitalization.

Manic Episode

During a manic episode (Boxes 101.2 and 101.3), the disturbance in mood must be severe enough to include psychosis, the need for hospitalization, or marked impairment in functioning. Bipolar disorders are much less common than major depressive disorder. The overall prevalence of a manic episode is about 2% in both women and men.

In many cases, manic patients are brought to the ED by someone else (eg, family, police, or emergency medical services). Patients who are experiencing a manic episode may present as gregarious, humorous, and engaging, which may suddenly alternate with belligerence and irritability. Patients may display pressured speech, in which they keep talking, often rapidly and loudly without pauses between thoughts or sentences, and are difficult to interrupt. The thought process in mania is characterized by illogical associations and flight of ideas. An inflated self-esteem and grandiose delusions may lead them to also be argumentative, impatient, and condescending. Grandiosity often centers on very broad dramatic or universal themes, such as religion or politics. The patient may describe a massive undertaking, such as “uniting the world’s churches” or “solving world poverty.” These severe symptoms are usually accompanied by a profound lack of insight. Despite obvious altered behavior, impaired judgment, and poor impulse control, the patient may insist that there is nothing wrong or blame problems on others.

Manic patients have decreased or no need for sleep and typically report being awake for days. They may be involved in a massive project (eg, writing a novel), may completely disregard consequences of actions, may have difficulty with spending (eg, credit cards revoked), and may engage in risky behavior (eg, sexual liaisons with strangers, risky driving). Whenever possible, a corroborating history should also be obtained from family or others who know of the patient’s behavior.

Manic patients may present as trauma patients, injured by an action reflecting the patient’s grandiosity (eg, attempting to fly), impulsivity, or belligerence (eg, fighting, resisting arrest). A manic episode may be punctuated by abrupt periods of tearfulness and profound depression, including suicidal ideation. When

---

**Summary of Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition, Criteria for a Manic Episode**

A. Distinct period of abnormally and persistently elevated, expansive, or irritable mood, and abnormally and persistently increased goal-directed activity or energy lasting at least 1 week (or any duration if hospitalization is necessary).

B. During the period of mood disturbance and increased energy or activity, three or more of the following symptoms have persisted (four, if the mood is only irritable) and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity
   2. Decreased need for sleep (eg, feels rested after only 3 hours of sleep)
   3. More talkative than usual or pressure to keep talking
   4. Flight of ideas or subjective experience that thoughts are racing
   5. Distractibility (ie, attention too easily drawn to unimportant or irrelevant external stimuli)
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation
   7. Excessive involvement in pleasurable activities that have a high potential for painful consequences (eg, buying sprees, sexual indiscretions, foolish investments)

C. Mood disturbance is sufficiently severe to cause marked impairment in occupational functioning or social activities or to necessitate hospitalization to prevent harm to self or others, or psychotic features are present.

D. Symptoms are not caused by direct physiologic effects of a substance (eg, drug of abuse, medication) or a general medical condition (eg, hyperthyroidism).

depressive and manic features occur concurrently in such a manner, the disorder is termed mixed or bipolar, mixed phase.

**Cyclothymic Disorder**

Cyclothymic disorder is characterized by chronic mood swings that do not meet criteria for a hypomanic or depressive episode. The mood episodes must occur over at least 2 years, present for at least half the time, and the individual cannot be symptom free for more than 2 months at a time. 1

**Mood Disorders Caused by a General Medical Condition**

This diagnosis requires a prominent and persistent period of depressed mood or anhedonia that predominates the clinical picture, with evidence that the disturbance is the direct pathophysiological consequence of a medical condition, and not better explained by another mental disorder or occurring during the course of delirium. 1 Bipolar disorder requires a prominent and persistent period of abnormally elevated, expansive, or irritable mood; and abnormally increased activity or energy that predominates the clinical picture, with evidence of direct pathophysiological consequence of another medical condition, and it is not better explained by another mental disorder or occurs during the course of delirium. 1

Certain medical illnesses have a well-known association with mood disorder. In Parkinson's disease, electrical stimulation to a certain area of the substantia nigra alleviates symptoms of depression. Stimulation of an area only 2 mm away can cause acute reversible symptoms of depression, such as crying, not wanting to live, and hopelessness. Parkinson's disease has a well-known association with depression, with up to 40% of patients demonstrating major depression.

Certain malignant neoplasms have a well-known association with depression, including pancreatic carcinoma, brain neoplasm, and disseminated malignant disease (eg, lymphoma). Coronary artery disease, myocardial infarction, stroke, end-stage renal disease, acquired immunodeficiency syndrome, several endocrine diseases, and connective tissue disease are also associated with major depressive disorder. After a myocardial infarction, patients with depression have a 3.5-fold increase in cardiovascular mortality compared with nondepressed patients. The development of stroke, diabetes, and osteoporosis is more likely in patients with depression than in those who are not depressed.

Depression related to medical conditions may be different in some respects from primary depression and responds less favorably than primary depression to antidepressant medication.

**Mood Disorders Caused by Medications or Other Substances**

These are very similar to mood disorders caused by medical conditions, with the exception of the symptoms must develop during or soon after substance intoxication or withdrawal, or after exposure to a medication capable of producing the symptoms. 1

Many medications are associated with symptoms of mood disorders. Multiple antihypertensives, anticonvulsants, and hormones have been associated with depressive symptoms, and certain antibiotics and steroids are associated with manic symptoms. Intoxication with or chronic heavy use of alcohol, sedatives, hypnotics, anxiolytics, narcotics, and other depressants can cause symptoms of a major depressive episode. Stimulants such as cocaine, phencyclidine, hallucinogens, and amphetamines can cause symptoms of a manic episode. Mood disorder symptoms can also develop during withdrawal. To qualify for this diagnosis, the symptoms must not occur exclusively during a course of delirium, must cause significant distress or impairment of functioning, and must develop within a month of either substance intoxication or withdrawal. When the mood disorder predates the period of substance abuse or lasts longer than 1 month after the period of abuse, the diagnosis may be an underlying mood disorder, such as a major depressive disorder or bipolar disorder, with a comorbid substance abuse or dependence diagnosis.

**DIFFERENTIAL DIAGNOSIS**

**Medical Disorders, Medications, and Substance Abuse or Withdrawal**

Medical disorders, medications, and substance abuse or withdrawal can either cause or mimic mood disorders. The patient with symptoms and signs of depression may have an unrecognized malignant neoplasm or sedative intoxication. Differential diagnostic considerations for manic symptoms include stimulant abuse (eg, cocaine, amphetamines), hallucinogen abuse, alcohol or sedative withdrawal, delirium, hyperthyroidism, and other medical conditions causing agitation. See the previous section for further information. Patients may be treated with antidepressant medication for a variety of disorders other than depression, such as anxiety, obsessive-compulsive disorder, post-traumatic stress disorder, pain syndromes, smoking cessation, and vasodepressor syncope.

**Grief and Bereavement**

Grief and bereavement are normal human reactions to the acute loss of another person, health, social position, or job. The period of mourning is characterized by sadness, diminished sense of well-being (somatic complaints), sleeplessness, and sadness triggered by thoughts of the loss. Normal grief, however, does not include guilt, loss of self-esteem, feelings of worthlessness, suicidal intent, psychomotor retardation, or occupational dysfunction. The duration of normal grief and bereavement differs among cultures and among individuals within cultures, but severe symptoms normally resolve within 6 to 12 months.

**Adjustment Disorders**

Adjustment disorders are behavioral or emotional disorders that occur in response to an identifiable stress or stressors, with marked distress that is out of proportion to the severity of the stressor. The emotional component can involve sadness, low self-esteem, suicidal behavior, hopelessness, helplessness, or other self-threatening behavior. Acute adjustment disorder occurs within 3 months of the stressor and does not last longer than 6 months. 1 The stressors are typically not as severe as those precipitating bereavement reaction, and the responses are often more maladaptive.

**Borderline Personality Disorder**

Borderline personality disorder is characterized by unstable personal relationships, unstable self-image, and self-destructive behaviors. The disorder may include chronic feelings of emptiness, which may be misdiagnosed as depression, or reactivity of mood, which may be mistaken for mania or hypomania. These patients typically live lives of crisis and constant conflict.

**Dementia**

Dementia can be confused with depression but is characterized by abnormal mental status, including abnormalities in tests of memory, calculation, and judgment.
DIAGNOSTIC TESTING

History and physical examination should focus on determining if the patient has a mood disorder or the possibility that drug abuse, medications, or a general medical condition may be responsible for the patient’s condition instead. It is essential to identify medical conditions that may exacerbate a psychiatric presentation. The psychiatric history should ask about current symptoms, precipitating events (eg, job loss or relationship), past psychiatric and substance history, history of self-harm or suicide attempts, and identification of support systems. Even if not suggested by the patient, careful questioning of suicidal thoughts is necessary. If possible, history should be confirmed by speaking with the patient’s regular health care providers and interviewing family, friends, or eyewitnesses to the events that precipitated the ED visit. A tentative diagnosis can be established by use of DSM-5 criteria. Laboratory tests to investigate medical conditions may be necessary based on the specifics of the clinical presentation, but no tests can confirm or exclude mood disorders. Patients with new symptoms compatible with mood disorders need a more extensive medical and psychiatric investigation than those with a known disorder.

Fig. 101.1. Protocol for treatment of agitation. BZN, Benzodiazepine; CNS, central nervous system; ETOH, ethyl alcohol; IM, intramuscular; IV, intravenous. *There is strong evidence that doses above 3 mg (per day) in patients with delirium are associated with significant risk of extrapyramidal side effects (EPS), so patients receiving more than 3 mg/day should be assessed carefully for EPS. †See U.S. Food and Drug Administration (FDA) guidelines. ‡If an antipsychotic alone does not work sufficiently, add lorazepam 1 to 2 mg (oral or parenteral). (Redrawn from Wilson MP, Pepper D, Currier GW, et al: The psychopharmacology of agitation: consensus statement of the American Association for Emergency Psychiatry Project BETA Psychopharmacology Workgroup. WJEM 13[1]:26-34, 2012.)
Patients presenting with mood disorder symptomology are frequently in crisis, often overwhelmed, and frankly scared. The ED is a chaotic, stimulating environment that may cause or exacerbate the patients’ level of agitation. Creation of a safe and stable environment for the patient is a high priority. The patient with an acute manic episode may be disruptive, refuse medical evaluation, and make repeated attempts to leave the ED. The initial step in treating such a disruptive patient is to offer assistance in reducing the agitation. A recent consensus guideline produced by the American Association for Emergency Psychiatry, noted keys to de-escalation. One key is offering anxiolytic medication early in the patient’s presentation. If de-escalation techniques and medication do not resolve the agitation, the patient may need to be placed in seclusion or restraints for his or her safety and that of others. This is a last resort after other de-escalation measures have failed. Chapter 189 discusses the use of seclusion and restraints in the ED. If a medical cause for agitation is found, treatment is aimed at the underlying cause (e.g., oxygen for hypoxic delirium). Often in the ED, treatment may need to begin prior to the cause of the agitation being fully recognized. Figure 101.1 shows a simple algorithm for approaching the agitated patient.

Treatment of depression in the ED is more controversial. Selective serotonin reuptake inhibitors (SSRIs) and serotonin norepinephrine reuptake inhibitors (SNRIs) are the main treatments for depression. For the patient who is awaiting inpatient psychiatric placement, these medications could be started in consultation with the admitting service. If the patient has a mild to moderate depression, not requiring hospitalization, they may be started on an SSRI as long as they have close follow-up arranged. SSRIs are known to have a myriad of side effects that can lead to premature discontinuation. For the patients who are already on psychotropic medications but have discontinued them for some reason, it is reasonable to restart these medications in the ED.

A non-agitated manic patient may be able to inform the treatment team about what has worked well in the past. There are two medication choices for acute mania: antipsychotics and mood stabilizers. All of the atypical, or second generation, antipsychotics have been approved to treat acute mania as monotherapy or as an adjunctive therapy, except paliperidone and iloperidone. Lithium, valproic acid/divalproate, and carbamazepine are the most well studied mood stabilizers. Lithium and carbamazepine need to be titrated, but valproic acid can be loaded in the ED at 20 to 30 mg/kg a day (divided dose) in a healthy person with normal liver function.

The atypical antipsychotic medications including ziprasidone, risperidone, olanzapine, aripiprazole, and quetiapine, cause fewer side effects (such as, acute dystonia) than conventional antipsychotic agents. Oral doses should be offered first, and several agents, including risperidone, olanzapine, and aripiprazole, are available in rapidly dissolving tablet form. Three are available as an intramuscular injection: ziprasidone (Geodon), olanzapine (Zyprexa), and aripiprazole (Abilify). Ziprasidone 10 mg to 20 mg is effective; however, its use is limited to 40 mg per 24 hours. Olanzapine 2.5 mg to 10 mg is effective but is associated with postural hypotension, and it is not recommended in combination with parenteral benzodiazepines because of the risk of cardiopulmonary depression. Aripiprazole is the newest agent and at doses of 9.75 mg to 15 mg seems to be the least sedating of the atypicals, but it is more likely to cause nausea and vomiting. It is valuable to obtain psychiatric consultation during the initiation of agitation treatment, because these patients will generally require significant ED treatment or psychiatric hospitalization.

**DISPOSITION**

To determine the appropriate disposition for patients presenting with a mood disorder, a suicide risk assessment is required. The Substance Abuse and Mental Health Services Administration developed a practical tool referred to as the Suicide Assessment Five-Step Evaluation and Triage (SAFE-T). Current suicidal thoughts, risk factors and protective factors should be identified, as well as past suicidal thoughts, plans, or acts. Chapter 105 provides an in-depth discussion of suicide assessment. It is only after considering this information that an appropriate intervention can be determined. With the help of social workers or a mental health worker, many patients can be safely discharged home with close follow-up. Patients receiving initial treatment in the ED, without a proper handoff to outpatient care, are at an increased risk for return. If available, it is preferred that a social worker or mental health worker connect discharged patients with outside agencies and services, rather than providing patients with a referral list.

**KEY CONCEPTS**

- Patients with apparent mood disorders should be evaluated for medical disorders, medication effects, or substance abuse or withdrawal because these conditions can mimic both depression and mania.
- Mood disorders should be suspected in patients with multiple, vague, nonspecific complaints and in patients who are frequent, heavy users of medical care.
- The differentiation of depression and dementia in elders can be difficult but is important because depression often responds dramatically to treatment.
- Patients with mood disorders should be assessed for their suicide potential.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
1. Elevated cortisol levels.
2. Decreased dopamine levels. The HPA axis may also be altered with epinephrine and serotonin. Data are also emerging that suggest macologic management is directed towards depressed levels of norepinephrine.

3. The central biochemical features toward which pharmacologic management is directed are decreased dopamine activity. Data are also emerging that suggest depressed levels of norepinephrine and serotonin. Data are also emerging that suggest decreased dopamine levels. The HPA axis may also be altered with increased cortisol levels.

4. Which of the following imbalances of central nervous system neurotransmitters is seen in patients with clinical depression?
   A. Decreased hypothalamic-pituitary-adrenal (HPA) activity
   B. Depressed serotonin levels
   C. Elevated gamma-aminobutyric acid (GABA) levels
   D. Elevated norepinephrine levels
   E. Unchanged dopamine levels

   Answer: B. Depression in children and adolescents can be manifested as ADD. Somatic complaints are a common feature of children and adolescents presenting with depression, but the diagnostic criteria are not different. Geriatric depression may be manifested in a manner similar to dementia (pseudodementia), but unlike dementia, the depression is highly treatable and reversible once it is recognized.

5. Which of the following statements is most true?
   A. Antipsychotic agents are not effective.
   B. Hallucinations would be atypical.
   C. If treated, intravenous valproic acid is indicated.
   D. Initiating treatment in the ED is not indicated.
   E. Multiple antibiotics can cause this clinical picture.

   Answer: E. This patient has a fairly classic presentation for acute mania with pressured speech, distractibility, grandiosity, increased involvement (in this case with work), and decreased need for sleep. Multiple drugs may precipitate this, including acyclovir, isoniazid, sulfonamides, the floxins, and chloroquine. An acute manic episode may be manifested with hallucinations and mimic an acute psychosis. ED treatment is usually indicated for this disorder. Acute stabilization is generally effective with major tranquilizers, such as haloperidol.

CHAPTER 102

PRINCIPLES

Background

Anxiety is a specific unpleasurable state of tension that forewarns the presence of danger, real or imagined, known or unrecognized, and is often verbalized as an intense feeling of worry. Up to a point, anxiety can improve performance; however, extreme responses can lead to deterioration of performance. As the level of dysfunction increases, the patient is much more likely to have a true anxiety disorder.

Acute anxiety is common in emergency department (ED) patients who have primary anxiety disorders, concomitant anxiety disorders, and crisis situations. It is helpful to differentiate the origin of anxiety to offer appropriate treatment. As an example, many medical conditions mimic anxiety disorders, and up to 42% of patients initially thought to have anxiety disorders are later found to have organic disease.

Emergency clinicians should be able to distinguish between anxiety disorders and medical illness (Box 102.1) and, if necessary, treat both entities. Because anxiety states cause an increase in metabolic demands, they can cause a marginally compensated organ system to fail. In a recent study, 48% of patients presenting for pain complaints were found to have moderate to severe anxiety and only 1% received anxiety treatment.1

Epidemiology

Approximately 40 million Americans older than 18 years old, nearly 20% of adults, are affected by anxiety disorders each year. Many primary care patients have significant mood and anxiety symptoms, such as panic disorders, generalized anxiety disorders (GADs), and depression, but nearly half of these symptomatic patients never receive appropriate treatment. Patients with chronic illness and those who make frequent medical visits have higher rates of anxiety and depression. The prevalence of anxiety disorders surpasses that of any other mental health disorder, including substance abuse. There is a close relationship between alcohol abuse and anxiety disorders.

The incidence of specific anxiety disorders varies: specific phobia is 7% to 9%, social anxiety is 7%, panic disorder is 3%, and GAD is 3%.2 The lifetime risk for post-traumatic stress disorder (PTSD) is about 9%, but the 12-month prevalence is approximately 4%. Substance or medication-induced anxiety and anxiety due to a medical condition have an unknown prevalence but may be relatively high in those seeking emergency medical care.

A different form of anxiety, related to fear of suffering from an illness, now known as illness anxiety disorder (formerly hypochondriasis), may be as high as 8% in ambulatory medical populations.3 Patients may present with a physical complaint and try to disguise their anxiety rather than bear the perceived stigma associated with psychiatric complaints, and they are distinct from patients who have a somatoform disorder.

Pathophysiology

There are many forms of anxiety disorders, and the precise mechanisms underlying the development of anxiety have not been fully established. The serotonin system and the noradrenergic systems are common pathways implicated in anxiety. It is believed that low serotonin system activity and elevated noradrenergic system activity are involved, and thus selective serotonin reuptake inhibitors (SSRIs) and serotonin-norepinephrine reuptake inhibitors (SNRIs) are frequently used as treatment. There is also considerable comorbidity with depressive disorders, with evidence showing genetic and neurobiologic similarities, especially related to serotonin.

The well-established effectiveness of benzodiazepines in the treatment of anxiety has led to the study of the gamma-aminobutyric acid (GABA) system and its relationship to anxiety. GABA is the principal inhibitory neurotransmitter in the central nervous system, and benzodiazepines act on the GABA receptor. Studies have focused on the role that corticosteroids may play in fear and anxiety. Steroids are thought to induce chemical changes in select neurons that strengthen or weaken certain neural pathways to affect behavior under stress.4

Family research suggests that genetic factors play a role in anxiety, but the precise nature of the inherited vulnerability is unknown. Five major anxiety disorders, panic disorder, GAD, phobias, obsessive-compulsive disorder (OCD), and PTSD, share genetic and environmental risk factors. Psychological and environmental factors also contribute in the generation of anxiety in biologically predisposed individuals.

CLINICAL FEATURES

Many patients seeking care in the ED experience anxiety related to encountering internal and external dangers, such as assaults on body integrity in the form of uncomfortable procedures and forced intimacy with strangers. In addition, the patient may experience uncertainty about his or her illness and the potential implications of the illness.

Anxiety may be a manifestation of a physical disorder or an expression of an underlying psychiatric disorder. It may be difficult to make the distinction between anxiety as a symptom and anxiety as a syndrome in the ED. The physical symptoms of autonomic arousal (eg, tachyphoea, tachycardia, diaphoresis, light-headedness) may be the only manifestations of anxiety. Classic panic disorder symptoms of chest pain, shortness of breath, and the sense of impending doom will often lead the patient to the ED, especially if it is the very first episode.5 Anxiety associated with medical disorders is more likely to be manifested by physical symptoms and less likely to be associated with avoidance behavior (see Box 102.1).
Predictors of Anxiety Caused by an Underlying Medical Issue

Onset of anxiety symptoms after 35 years old
Lack of personal or family history of an anxiety disorder
Lack of childhood history of significant anxiety, phobias, or separation anxiety
Lack of avoidance behavior
Absence of significant life events generating or exacerbating the anxiety symptoms
Poor response to anti-anxiety agents

Characteristics of a Panic Attack

Abrupt surge of intense fear or discomfort that reaches a peak within minutes, in which four or more of the following occur:
- Palpitations
- Sweating
- Trembling
- Shortness of breath or feeling of being smothered
- Feeling of choking
- Chest pain or discomfort
- Nausea or abdominal distress
- Feeling dizzy or light-headed
- Chills or heat sensations
- Paresthesias
- Derealization or depersonalization
- Fear of losing control or going “crazy”
- Fear of dying

Generalized Anxiety Disorder

GAD is defined as excessive worry that occurs most days over a 6-month period involving several events or activities. The anxiety must cause significant distress or impairment. GAD has been linked to overuse of medical services and often is not recognized, which leads to ineffective treatment.

Post-Traumatic Stress Disorder

PTSD is caused by experiencing or witnessing a highly traumatic event. Those with PTSD manifest symptoms of re-experiencing the event, avoidance of triggers, changes in cognition and mood, and changes in arousal and reactivity (Box 102.3). Rates of PTSD are higher among military veterans and those whose occupation involves risk of traumatic exposure. ED staff are also at risk for experiencing PTSD related to unusual traumatic events and unexpected deaths and, unfortunately, the support for this tends to be minimal.

Specific Phobias

A phobia is an irrational fear that results in avoidance. Phobia becomes a disorder when it interferes with day-to-day function in an individual’s life. A social phobia, now termed social anxiety disorder, is characterized by clinically significant anxiety about one or more social situations in which the individual may be scrutinized. This fear often leads to avoidance behavior for such activities, such as public speaking, performing, visiting, using public showers or restrooms, or eating in public places.

Obsessive-Compulsive Disorder

OCD is characterized by recurrent, obtrusive, unwanted thoughts (obsessions), such as fears of contamination, or compulsive behaviors or mental acts (compulsions) that a person feels compelled to perform, such as handwashing or counting. OCD is characterized by clinically significant anxiety disorder because (1) anxiety or tension is often associated with obsessions and resistance to compulsions, (2) anxiety or tension is often immediately relieved by yielding to compulsions, and (3) OCD often occurs in association with other anxiety disorders. In summary, the obsessions and intrusive thoughts increase anxiety, and the compulsions and repetitive behaviors decrease anxiety but with significant disruption of one’s life.
Somatic Symptoms and Related Disorders

Although not necessarily considered anxiety disorders, this group of disorders has an undefined, but established link to anxiety and depressive disorders. This group includes somatic symptom disorder, illness anxiety disorder (formerly hypochondriasis), conversion disorder (formerly functional neurological symptom disorder), and psychological factors affecting other medical conditions. With somatic disorders, the patient will complain about one or more physical symptoms, which cause impairment notwithstanding a negative evaluation. These symptoms are not intentionally feigned, as in the case of malingering or factitious disorder. A high utilization of medical services is correlated with these disorders, independent of comorbidity. Patients with panic disorder, however, seek at least as much psychiatric attention as do those with somatoform disorders.

DIFFERENTIAL DIAGNOSIS

In patients who present with predominant symptoms of anxiety, even when the patients have known anxiety disorders, before considering which of the previously discussed Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition (DSM-5) anxiety-related diagnoses the patient might have, the emergency clinician should first consider the possibility of medical and pharmacologic-related conditions associated with anxiety. Patients with anxiety disorders may present with apparent physical disease, and many physical diseases are strongly associated with symptoms of anxiety. Several factors help distinguish an anxiety syndrome caused by an underlying medical issue from a primary anxiety disorder (see Box 102.1). Anxiety disorder classifications in the DSM-5 include anxiety caused by another medical condition.6

Because anxiety may be the most obvious symptom of an underlying disease or condition, the patient should be evaluated for exacerbation of known preexisting disease, as well as for the onset of new illness, because anxiety increases the risk of acute medical exacerbation of chronic illness.

The classic scenarios of pulmonary embolism and hyperthyroidism causing anxiety are well documented. Post–myocardial infarction patients with anxiety have poorer outcomes than those without documented anxiety. Patients with respiratory diseases, such as asthma and chronic obstructive pulmonary disease, often have anxiety associated with long-standing illnesses. In addition, many of the medications used to treat these illnesses may induce anxiety. One of the most common medical causes of anxiety is alcohol and drug use from either intoxication or, more typically, withdrawal states.

Cardiac Diseases

Approximately 25% of patients with chest pain who present to the ED have panic disorder. Their disorder often goes undiagnosed, resulting in multiple visits and expensive cardiac evaluations. Symptoms of myocardial infarction and angina pectoris may include crushing chest pain, shortness of breath, nausea, palpitations, heavy perspiration, and a feeling of impending death. These are also the primary symptoms of acute anxiety, but the pain is usually described as atypical, and patients are generally female and younger. Because of the morbidity and mortality of cardiovascular disease, a patient warrants a full cardiac evaluation when the differentiation between myocardial infarction and acute anxiety is unclear.

Cardiac dysrhythmias can cause palpitations, discomfort, dizziness, respiratory distress, and syncope. A panic attack has similar symptoms. Fortunately, most dysrhythmias can be documented and characterized on cardiac monitors or by electrocardiography. Mitral valve prolapse syndrome can be associated with palpitations and panic attacks indistinguishable from a panic disorder. Benzodiazepines can be used to provide symptomatic relief to patients who experience chest pain due to anxiety.

Endocrine Diseases

The most common endocrinologic conditions associated with anxiety states are hypoparathyroidism, hyperthyroidism and hypothroidism, hypoglycemia, pheochromocytoma, and hyperadrenocorticism. Anxiety is the predominant symptom in 20% of patients with hypoparathyroidism. Studies indicate a higher incidence of anxiety in the subset of patients with surgically removed parathyroid glands. Even though other symptoms may improve with supplementation, patients have been found to have significant depression, anxiety, somatization and phobic anxiety, even after being given calcium and vitamin D.

Anxiety symptoms are seen in up to 40% of diabetics, and 14% of diabetic patients suffer from anxiety disorders. There is evidence that diabetics who are treated with antianxiety medication not only reduce their anxiety but also decrease their glycosylated hemoglobin levels and high-density lipoprotein concentration. One study found that diabetics with mental health problems were less likely to improve glycemic control and suggested that psychological evaluation and therapy be used adjunctively.

Pheochromocytomas are rare tumors that produce elevated levels of catecholamine in the body. Pheochromocytoma attacks may manifest similar to panic attacks and can be precipitated by emotional stress. Elevated urinary catecholamine or plasma metanephrine levels confirm a pheochromocytoma.

Hyperthyroidism is one of the most frequently encountered endocrine diseases associated with anxiety. As with panic disorders, hyperthyroidism is associated with acute episodic anxiety. Thyrotoxicosis causes anxiety, palpitations, perspiration, hot skin, rapid pulse, active reflexes, diarrhea, weight loss, heat intolerance, proptosis, and lid lag. A substantial portion of patients continue to have psychiatric manifestations even after treatment.

Psychiatric presentations can be the first sign of hypothyroidism, occurring as the initial symptom in 2% to 12% of reported cases along with deficits of impaired recent memory and learning. The severity of anxiety disorders in hypothyroid states is related to the rapidity of thyroid hormone level changes and not to the absolute hormone levels. In general, checking serum thyroid-stimulating hormone and free thyroxine levels will suffice in the ED to establish the diagnosis of thyroid disease.

Respiratory Diseases

Most conditions causing airway compromise or impairment of gas exchange do not mimic psychiatric disorders. However, some conditions that cause hypoxemia or hypercarbia may lead to the development of significant anxiety. Up to a third of the patients with chronic obstructive pulmonary disease meet the criteria for anxiety disorder.

Patients who have severe asthma are twice as likely to have an anxiety disorder and almost five times as likely to have a phobia compared with nonasthmatics. Acute dyspnea from a pure panic attack with good air movement and normal lung sounds is easily differentiated from an asthma attack, but studies consistently show that anxiety disorders increase asthma morbidity and mortality.

Acute shortness of breath in any patient should not be immediately attributed to anxiety, especially because pulmonary embolism can present with only shortness of breath as the major symptom. Fortunately, pulmonary embolism can almost always
be distinguished by history and physical examination, assessment of risk factors for thromboembolic disease, and laboratory testing (eg, pulse oximetry, electrocardiography, chest radiography, and D-dimer assay) as indicated.

Neurologic Disorders

Many neurologic conditions are associated with anxiety symptoms. For example, stress is one of the most common reported causes of seizures. Those who report stress as a trigger tend to have higher scores on anxiety tests, and the stress may be either acute or chronic. Temporal lobe seizures, complex partial seizures, tumors, arteriovenous malformation, and ischemia or infarction have all been reported with panic attacks. Anxiety disorders also occur in the aftermath of traumatic brain injury (TBI). Approximately 23% of those who sustain a mild TBI are at risk for developing an anxiety disorder; this is frequently found in military personnel. In Huntington’s disease, anxiety is the most common prodromal symptom. Anxiety occurs in up to 40% of patients with Parkinson’s disease and up to 37% of patients with multiple sclerosis. Similarly, anxiety symptoms are common in moderate Alzheimer’s disease.

Drug Intoxication and Withdrawal States

Amphetamines, cocaine, and other sympathomimetic drugs are abused for their stimulant and mind-altering properties. Patients often present agitated, anxious, or when these drugs are taken in large doses and with prolonged use. Caffeine is a very commonly used stimulant, and studies suggest that 240 mg to 300 mg of caffeine per day should be the upper limit of healthy consumption. When consuming higher doses, considered caffeine intoxication, restlessness, nervousness, excitement, insomnia, diuresis, gastrointestinal disturbance, tachycardia, psychomotor agitation, as well as other unpleasant symptoms may occur. The acute symptoms of caffeine intoxication and GAD are almost identical.

Marijuana users believe that the drug reduces their anxiety, but some experience a depersonalization that provokes severe anxiety, fearfulness, and symptoms of agoraphobia. Cannabis intoxication is associated with behavioral or psychological changes, such as anxiety, and physical signs, such as conjunctival injection, dry mouth, and tachycardia. Lysergic acid diethylamide (LSD), phencyclidine (PCP), and ecstasy (3,4-methylenedioxy-methamphetamine [MDMA]) are hallucinogens that can produce anxiety and paranoia from chronic use or “bad trips.” Flashbacks affect some users of LSD; the person may experience the symptoms of anxiety and paranoia a few weeks or months after use.

Sedative, hypnotic or anxiolytic drugs (eg, benzodiazepines, barbiturates) are taken to relieve anxiety or sleeplessness, but their discontinuation can cause sedative withdrawal and rebound anxiety. The severity of the withdrawal syndrome depends on the drug, dosage, duration of use, and speed of elimination. Symptoms include hyperalertness, motor tension, muscle aches, agitation, anxiety, insomnia, tremulousness, nausea, vomiting, convulsions, delirium, and even death.

Although antidepressants are rarely abused, their abrupt cessation can cause a discontinuation syndrome, which may present as sensory and gastrointestinal-related symptoms, insomnia, lethargy, and extreme anxiety.

Alcohol withdrawal can appear 6 to 12 hours after the last drink or significant reduction in consumption. Patients often have a detectable serum alcohol level at this time. Anxiety is one of the first and most prominent symptoms and is seen within 24 to 48 hours of the withdrawal state. Symptoms of anxiety, insomnia, and autonomic dysfunction can last up to 3 to 6 months following alcohol withdrawal.

DIAGNOSTIC TESTING

The initial history and physical examination should focus on the presenting complaints to determine if the patient has an anxiety disorder or anxiety caused by drug abuse, medication use, or a general medical condition. The psychiatric history should, at minimum, include current symptoms, precipitating events (eg, job loss or relationship), past psychiatric and substance history, history of self-harm or suicide attempts, and identification of support systems. A thorough risk assessment for suicidality is key. Among ED patients, panic attacks have been found to be closely associated with suicidal ideation (43%) and intent (55%). Chapter 105 discusses suicide risk assessment.

A physical examination focused on the area of complaint is necessary, even when there is no overt evidence of physical disease. Abnormal vital signs suggest an organic medical cause of the anxiety symptoms. Laboratory tests may be necessary based on the clinical presentation, but no tests can confirm or exclude anxiety disorders. Patients with new symptoms require a more extensive medical and psychiatric investigation than those with a known disorder.

MANAGEMENT

The patient should be placed in a quiet area for evaluation. Some patients calm when they are removed from a chaotic ED environment. If that is not possible, reducing environmental stimulants, such as turning down the lights, can be helpful. If the emergency clinician encounters difficulty in calming the patient, supportive family members may help.

Pharmacologic Treatment

Use of oral, intravenous, or intramuscular medication may be necessary when an anxiety state is so out of control that there is a significant threat to safety of self or others. Medication may also be appropriate for the anxious patient experiencing a significant medical illness or undergoing a medical procedure. Lorazepam in small increments can be helpful in alleviating the anxiety associated with substance withdrawal states. Midazolam reduces anxiety and increases amnesia for ED procedures.

SSRIs and SNRIs have become first-line treatment of most anxiety disorders because of their broad spectrum of efficacy and high tolerability by most patients. They have a lower potential for dependence and are safer than older classes of antidepressants and anxiolytics. Improvement is usually seen in 4 to 6 weeks, but doses may have to be adjusted. Initiation of longer term medication is usually done by primary care physicians or psychiatrists. It is important to start the patient with low doses of SSRIs (usually half the normal starting doses used for depression) and to arrange for frequent short-term follow-up visits, because an initial increase in anxiety may be seen. We do not recommend that these medications be started in the ED unless accompanied by patient education and close follow-up with a primary care physician or psychiatrist.

Benzodiazepines can be prescribed for motivated patients with acute exogenous anxiety for time-limited stress. Benzodiazepines are an attractive alternative to the delayed response of an SSRI when an immediate reduction of symptoms is desired or a short-term treatment is needed. Benzodiazepines have a role in emergency medical treatment, but their use is questionable for long-term treatment. In most circumstances, benzodiazepines should be prescribed for a week or less. Patients who do not improve within a week are unlikely to benefit from the drug. Prescribers will commonly use a benzodiazepine for the first week while initiating SSRI or SNRI treatment. Patients with a history of alcoholism or drug abuse, who are excessively and emotionally
therapy may be helpful for individuals whose psychological makeup, coping style, interpersonal dynamics, and situational stressors contribute to their pathologic anxiety. The use of supportive, insight-oriented family therapy is helpful when these factors appear prominently in the patient’s presentation. Cognitive-behavioral therapy helps the patient correct the cognitive misperceptions and overreactions that occur. Cognitive-behavioral therapy is very effective but requires commitment from the patient. Meditation, biofeedback, and suggestive hypnosis may also have a role in long-term treatment.

**DISPOSITION**

Patients receiving initial treatment in the ED, without a proper handoff to outpatient care, are at an increased risk for return. If available, it is preferred that a social worker or mental health worker connect discharged patients with outside agencies and services, rather than providing patients with a referral list. Most patients with an anxiety disorder can be safely discharged with close primary care physician or psychiatrist follow-up. Patients with an anxiety disorder associated with suicidal or homicidal ideation or with severe depression require urgent psychiatric attention and admission to the hospital.

**KEY CONCEPTS**

- Patients who present with predominant symptoms of anxiety may be suffering from medical disorders, medication effects, or substance abuse or withdrawal.
- Anxiety may accompany the onset of serious medical disease, cause significant metabolic demands, and stress a marginally compensated organ system.
- Anxiety caused by physical illness is usually suggested by the patient’s physical findings but may require testing to further delineate the cause.
- Oral, intravenous, or intramuscular medication may be necessary for patients who are a significant threat to themselves or others and for anxious patients with significant medical illness.
- Limited benzodiazepine therapy may be helpful for select patients.

CHAPTER 102: QUESTIONS & ANSWERS

102.1. Which of the following is the most common mental health disorder?
A. Anxiety
B. Bipolar
C. Depression
D. Schizophrenia
E. Substance abuse

Answer: A. Many of these patients never receive appropriate care, in part because they choose to present with a physical complaint and disguise their anxiety. Patients with chronic illnesses have higher rates of anxiety and depression than the rest of the population.

102.2. What is the most common cause of organic anxiety, anxiety that results from a physiologic origin?
A. Adrenal disorders
B. Alcohol and drug use
C. Cardiac disease
D. Hyperthyroidism
E. Pulmonary embolism

Answer: B. This may be from intoxication or withdrawal states.

102.3. A 52-year-old woman presents with 2 months of recurrent episodes of anxiety, mild chest pain, subjective palpitations, hand paresthesias, and occasional muscle spasms. They have occurred weekly in the past but are now increasing in frequency. Her only past history is a thyroidectomy 4 months prior. She is taking levothyroxine (Synthroid) and had normal thyroid hormone levels. Laboratory evaluation shows sodium 141 mEq/L, potassium 4.1 mEq/L, creatinine 1.0 mg/dL, bicarbonate 26 mEq/L, chloride 100 mEq/L, and calcium 7.1 mg/dL; a complete blood count is normal. Which of the following should be the next step in her management?
A. Outpatient clonazepam
B. Parathyroid hormone level
C. Psychiatry consultation
D. Thyroid hormone levels
E. Urine drug screen

Answer: B. Anxiety is the predominant symptom in 20% of patients with hypoparathyroidism. Other symptoms include paresthesia, muscle cramps, and spasms. Most cases are idiopathic or due to inadvertent parathyroid gland harvest during thyroidectomy. The diagnosis is suggested by a low serum calcium and an elevated phosphate and is confirmed by a depressed parathyroid level.

102.4. Which of the following statements regarding anxiety and endocrine disorders is true?
A. Anxiety can often be traced to reactive hypoglycemia.
B. Anxiety is not a manifestation of hypothyroidism.
C. Diabetics treated with antianxiety agents have improved hemoglobin A1c levels.
D. Less than 5% of diabetics experience anxiety.
E. Patterns of diaphoresis in pheochromocytoma mimic those of a panic attack.

Answer: C. Approximately 15% of diabetics have an anxiety disorder. Treatment improves hemoglobin A1c levels. Anxiety due to reactive hypoglycemia is rare despite the common perception among patients. Pheochromocytoma causes whole body diaphoresis, whereas panic disorders primarily cause sweaty palms. Hyperthyroidism or hypothyroidism can cause significant anxiety manifestations. It is more related to the rate of change than the level of thyroid hormones.

102.5. A 23-year-old woman with a history of asthma presents with increasingly frequent episodes of panic attacks. Her medications are an inhaled beta-agonist and an intermittent steroid inhaler. She reports subjective increasing asthma severity as her panic episodes have worsened. When counseling the patient, which of the following statements is most correct?
A. Anxiety disorder in an asthmatic patient does not increase morbidity.
B. Anxiety does not precipitate asthma attacks.
C. Anxiety does not worsen airflow.
D. Asthmatics are more likely to have an anxiety disorder.
E. It is difficult to differentiate dyspnea related to asthma from anxiety.

Answer: D. Anxiety can precipitate and prolong an asthma attack. Morbidity and mortality are increased in asthmatic patients who have a coexisting anxiety disorder. Patients who have asthma are twice as likely to have an anxiety disorder and five times as likely to have a phobia. Acute dyspnea from “panic” dyspnea can be differentiated from asthma by clear lungs on auscultation.

102.6. Which of the following syndromes is not associated with anxiety?
A. Left hemispheric strokes
B. Multiple sclerosis
C. Right hemispheric strokes
D. Transient ischemia attack
E. All of the above can be associated with anxiety.
PART III  Medicine and Surgery  |  SECTION EIGHT  Psychiatric and Behavioral Disorders

Answer: E. Anxiety may be a component of seizures, tumors, arteriovenous malformations, and ischemic events. It may be the only manifestation of some disorders (eg, right hemispheric strokes and transient ischemic attacks [TIs]). The coexistence of anxiety plays an important role in the prognosis and impairment of stroke patients.

102.7. A 38-year-old woman with a long history of anxiety and panic disorder presents with anhedonia, melancholy, sleep disruption, crying episodes, and some hostility feelings. She has no current anxiety symptoms. Her only medication is clonazepam. She has no known medical illness. Which of the following statements regarding this patient’s symptoms is true?
A. Approximately 50% of patients with panic disorder develop major depression.
B. Depression with anxiety and hostility is usually refractory to treatment.
C. The first diagnostic step should be a thyroid panel.
D. The majority of patients with depression have panic attacks.
E. This is likely a drug-induced depression.

Answer: A. Approximately 50% of patients with a primary panic disorder will later develop major depression. Twenty percent of patients with depression have panic attacks. Depression with panic attacks is less responsive to treatment, but depression with anxiety and hostility responds well to antidepressants. Although benzodiazepines can exacerbate symptoms of depression, there is already a high spontaneous rate of depression with anxiety disorders.

102.8. Which of the following statements regarding benzodiazepine use and anxiety is true?
A. Benzodiazepines are first-line agents for anxiety disorders.
B. Several weeks of treatment are indicated after initial diagnosis.
C. Short-acting benzodiazepines produce a more severe abstinence syndrome.
D. They are particularly useful in patients with alcohol abuse.
E. Withdrawal rebound is less common than with selective serotonin reuptake inhibitors (SSRIs).

Answer: C. SSRIs are the first-line agents for anxiety and panic disorders, but the primary disadvantage is the several-week lag needed for maximal clinical benefit. Benzodiazepines work best for motivated, dependable patients when an immediate reduction of symptoms is indicated or a short-term treatment is necessary. Patients who do not benefit from benzodiazepines within a week are unlikely to do so. Patients with a history of alcoholism or drug abuse, who are excessively/emotionally dependent, or who become anxious from normal stress are at greater risk for dependency. Rebound withdrawal is more likely after short-acting agents.

102.9. A 29-year-old Caucasian female presents with excessive daytime somnolence. She states that she had been suffering from anxiety associated with her paralegal occupation, and 1 week ago her psychiatrist had started her on a 2-week course of once-daily benzodiazepine therapy, which she takes in the morning. Her anxiety symptoms are well controlled. She asks if you can change her to a new medication because the somnolence is significantly affecting her job performance. What would be the most appropriate course of action?
A. Counsel the patient that she should continue the medication as prescribed because she will soon adapt and the somnolence will likely subside.
B. Discontinue the benzodiazepine and refer her back to her psychiatrist.
C. Have her try dosing the benzodiazepine at bedtime, because this will likely continue to control her anxiety and limit daytime somnolence.
D. Switch the patient to a selective serotonin reuptake inhibitor (SSRI) and refer her back to her psychiatrist.
E. Switch the patient to a shorter-acting benzodiazepine.

Answer: C. Instituting an SSRI should be reserved for primary care physicians or psychiatrists who can monitor the patient more closely, because the response will be delayed. Some patients do adapt to the sedative effects of benzodiazepines but usually only after long-term use. Stopping the benzodiazepine may ultimately be necessary but at the risk of recurrent anxiety. Dosing benzodiazepines at bedtime may minimize daytime sedation and still provide an anxiolytic effect. Shorter-acting benzodiazepines produce a more severe abstinence syndrome when stopped abruptly, and thus most prescribers prefer longer-acting agents.

102.10. A 52-year-old male construction worker presents with chest pain. He states his symptoms began early this morning and have progressively worsened throughout the day. His symptoms include nervousness, tremors, chest pain, shortness of breath, and palpitations. He states that he has had anxiety for 30 years but has controlled it with the consumption of alcohol. He became unemployed 1 week ago, and his daily alcohol use has diminished significantly. His vital signs are blood pressure (BP) 185/95 mm Hg, heart rate 123 beats per minute, respiratory rate of 20 breaths per minute, and temperature of 98.9°F. His physical examination is remarkable for diaphoresis, tongue fasciculation, both resting and intention tremors, and mild psychomotor agitation while maintaining orientation with a congruent anxious mood and affect. What is the most likely etiology of this patient’s symptoms?
A. Acute alcohol withdrawal syndrome
B. Exacerbation of endogenous anxiety secondary to diminished alcohol intake
C. Exacerbation of exogenous anxiety secondary to change in employment status
D. Hypertensive emergency with acute coronary syndrome
E. Reactive anxiety secondary to the onset of chest pain

Answer: A. Hypertensive emergency is unlikely given the level of this patient’s BP. On the basis of the history alone, it may be difficult to differentiate organic versus functional anxiety or identify an exogenous trigger, but the abnormal vital signs and physical examination associated with a recent cessation of long-term alcohol consumption makes acute alcohol withdrawal the most likely cause. Given the significant morbidity associated with withdrawal states, this must be addressed acutely. Appropriate diagnosis and management of underlying psychiatric disease will be a secondary concern after the patient’s withdrawal is managed.
CHAPTER 103

Somatoform Disorders

Adria Ottoboni Winter

PRINCIPLES

Somatic symptom disorders (SSDs), formerly known as somatoform disorders, are described as the borderland between psychiatry and medicine and are responsible for some of the most frustrating and the least understood patient encounters in the emergency department (ED). As such, it is important that emergency clinicians recognize and treat this disorder appropriately to avoid patient suffering, unnecessary testing, iatrogenic injuries, and inappropriate resource utilization. Patients with SSD are often labelled as “difficult” patients, yet appropriate mental health referrals are not made, while psychological and psychosocial causes for their presentation remain unaddressed.

SSD patients present with multiple physical symptoms in the absence of detectable physical disease, and harbor excessive health concerns that are expressed emotionally, cognitively, and behaviorally. These patients perceive a wide range of severe symptoms including pain, gastrointestinal, cardiovascular, sexual, and pseudo-neurological symptoms, which cause inappropriate and persistent worry, distress, and social dysfunction. Biological, psychological, and psychosocial factors interact as precipitating, aggravating, and maintaining factors of psychopathology. Biological, psychological, and psychosocial factors interact as precipitating, aggravating, and maintaining factors of psychopathology. Somatization is best understood by focusing on the abnormalities in the patient’s response to their somatic symptoms, rather than on the absence of a discernible medical cause for those symptoms. The patient’s maladaptive response to somatic symptoms is the reason this behavior is classified as a psychiatric disorder. The major diagnosis in this diagnostic class, of which SSD is the most prominent, hinges on the existence of the patient’s distinctive abnormal thoughts, feelings, and behaviors in response to somatic symptoms.

Somatoform disorders because of their very nature and presentation have consistently been diagnoses that are difficult to make with any certainty, even after multiple visits with the same primary care physician. It is therefore a challenging diagnosis to make within the busy confines of a brief visit to the ED. For patients with functional symptoms, the strategy of pursuing a medical cause with invasive diagnostic procedures, unnecessary surgeries, and misdirected drug trials can be life-threatening, and the unwarranted costs of these measures strain limited medical resources.

SSD are typically more common in women of low socioeconomic status who present between 20 and 30 years old, with a high incidence of comorbid anxiety or depression. The diagnosis of SSD is made when there are persistent and clinically significant physical complaints that are accompanied by excessive and disproportionate health-related thoughts, feelings, and behaviors regarding these symptoms.

There has been much debate regarding how to name and define SSD patients, with the latest (fifth) version of the Diagnostic and Statistical Manual of Mental Disorders (DSM-5) reconceptualizing the category almost entirely. The previous criteria for SSD was criticized for being overly inclusive in certain areas and difficult to employ in either real life practice or research. The new diagnostic category of SSD in the DSM-5 is a radical construct change in which the number of symptoms plays only a minor role, while the distress of symptoms associated with psychological features and symptom consequences are emphasized.

The term somatization was frequently used in the psychiatric literature in the past but is now disapproved of as often as its predecessor hysteria. The DSM-5 no longer employs the term somatization and, in fact, has changed the criteria, as well as the nosology behind what was previously referred to as somatoform disorders. Recent publications refer to “medically unexplained physical or somatic symptoms,” rather than somatization.

The definitions of somatoform disorders have been a subject of controversy and criticism among psychiatrists as well as primary care providers since they were first included in the DSM-III as a speculative category. SSD had a central defining premise in the concept of “medical unexplained symptoms.” There were several problems with this, not the least of which was that many physicians and researchers found it difficult to define a disorder based on the lack of evidence, rather than on the presence of tangible findings.

The DSM-5 has attempted to solve many of these conflicts by restructuring and reconceptualizing the diagnosis. The major diagnosis in this diagnostic class, SSD, emphasizes that the diagnosis is made on the basis of distressing somatic symptoms plus maladaptive thoughts, feelings, and behaviors in response to these symptoms.

Although experts may disagree on how to classify SSD, none disagree on the clinical importance of recognizing and appropriately managing these patients. Emergency care providers are trained to focus on physical complaints and findings and to rule out life-threatening conditions. They may consciously or unconsciously avoid asking difficult questions that would make a psychiatric diagnosis apparent or suspect. They may also be wary of ascribing the entirety of a patient’s complaints to a psychiatric disorder and risk missing the subtle presentation of medical illness and subsequently retreat into further testing. Proper recognition and management of somatoform disorders is, however, an essential component in minimizing the suffering of these patients and avoiding unnecessary diagnostic testing and the concurrent misallocation of resources.

CLINICAL FEATURES

Somatic and related disorders encompass the diagnoses of SSD, as well as several other psychiatric diagnoses that all share a common feature: the experience of physical symptoms associated with significant distress and impairment that cannot be adequately explained by demonstrable physical pathology despite appropriate medical investigation (Box 103.1).

Hypochondriasis as a DSM classification has been eliminated, and the majority of these patients would now be classified within the DSM-5 as having illness anxiety disorder. Illness anxiety disorder is considered a less stigmatized and pejorative term, and describes patients with a persistent preoccupation with having a serious illness, very high levels of health anxiety, a complete absence or very mild somatic symptoms, and excessive
Consequently, physicians perceive illness anxiety disorder patients to dominate the doctor-patient relationship to feel more powerful control of their lives and will sometimes make an obvious effort to explain at length and in detail, using medical jargon. As part of their illness anxiety disorder, the patient with illness anxiety disorder commonly comes to medical attention with a history of physical or sexual abuse. Although the classic description of conversion disorder, and it causes clinically significant distress or functional impairment. The disorder can be further subcategorized into (1) weakness or paralysis; (2) abnormal movements; (3) swallowing symptoms; (4) dysphonia or slurred speech; (5) attacks or seizures; (6) anesthesia; and (7) visual, olfactory, or hearing disturbances. Typically, there is a sudden dramatic onset of a single symptom, simulating some nonpainful neurologic disorder for which there is no pathophysiologic or anatomic explanation. Some of these symptoms may provide gratification for unconscious dependency needs, whereas others may provide escape from painful emotional stimuli. Typical comorbid diagnoses include mood disorders, panic disorder, generalized anxiety disorder, post-traumatic stress disorder, dissociative disorders, and obsessive-compulsive disorders. Patients with functional neurological symptom disorder (conversion disorder) often have a history of physical or sexual abuse. Although the classic description of these patients is one of inappropriate lack of concern for the sudden neurological deficit (“la belle indifférence”), such presentations are, in fact, rare and should not be considered necessary for the diagnosis.

**DIFFERENTIAL DIAGNOSIS**

It is important to remember that there are psychiatric disorders other than SSD that are initially brought to medical attention with manifested somatic symptoms, including major depressive disorder and anxiety disorders. In addition, there are several medical diagnoses that can have very subtle presentations with multiple physical symptoms, including multiple sclerosis, porphyria, hyperparathyroidism, systemic lupus erythematosus, thyroid disorders, and Wilson’s disease. Other diagnoses to consider include anxiety, substance abuse disorders, personality disorders, and malingering (Box 103.2).

**DIAGNOSTIC TESTING**

It is challenging to evaluate a patient for potentially life-threatening disease while simultaneously entertaining a psychiatric diagnosis of SSD. Repetitive or extensive diagnostic testing rarely excludes organic disease with absolute certainty and may yield false-positive results. Testing should only be performed for diagnoses that are supported by a carefully performed history and physical examination. The exception to this rule is the neurological symptom disorder patient, previously termed conversion disorder. Several neurological diseases have subtle presentations, multiple sclerosis being a case in point. The pace of the ED and the limited scope of diagnostic evaluation may make it difficult to discern between neurological symptom disorder and neurological pathology with any confidence. It may require imaging studies and both neurologic and psychiatric consultations to avoid the misdiagnosis of a patient who requires intervention.

**MANAGEMENT**

The success or failure of the emergency clinician to deal with patients who have SSD will depend on his or her ability to establish a rapport with the patient. Patients with these disorders can be more challenging to care for than patients with most other psychiatric disorders, and therefore physician knowledge and attitudes are key. It is important to build and maintain rapport with the patient with SSD by listening carefully and encouraging the patient to describe their symptoms. After developing a sound rapport, legitimize the patient’s complaints and then limit diagnostic investigations to address only clear cut findings of medical illness that are based on a careful history and physical examination.

One should avoid confronting or challenging the SSD patient and instead, agree that there is a problem, and work with the patient to formulate a plan of care and referral. The priority is to listen and communicate an understanding of what the patient is feeling and the extent of the functional impairment that they are experiencing. If the provider acknowledges the legitimacy of the patients claim to illness and assures the SSD patient of ongoing care, limits may be set on the patient’s illness behavior. Suffering is a subjective phenomenon and, in that sense, is genuine in these patients. It is appropriate to legitimize the patient’s symptoms and then use diagnostic labels after considering the needs of the individual patient encounter. If one believes that the patient is...
Amenable to the potential diagnosis of SSD, naming the diagnosis itself can help build a therapeutic alliance with the patient. The components of the SSD diagnosis, somatic symptoms, health-related anxiety, preoccupation about health concerns, and dysfunctional illness behaviors have an array of beneficial treatments that may be tried, although typically at the discretion of the primary care provider or psychiatric consultant. The potential therapeutic endeavors include cognitive therapy, behavioral techniques, psychotherapies, and in some cases psychotropic medications. If a diagnosis of SSD is seriously considered by the emergency care provider, these patients will require referral to primary care and subsequently to psychiatric consultation for evaluation and management.

### Disposition

Patients with suspected SSD and those with a preexisting diagnosis of SSD should be referred to either their primary care physician or to psychiatry. They should be told that acute life-threatening diagnoses have been ruled out and that further testing and additional medications are not indicated at this time. It is appropriate to point out that continued care and periodic reassessment are indicated, although not in the ED. Patients with concurrent anxiety or depression should receive psychiatric consultation or referral, especially when they present with an acute decompensation of these symptoms.

### KEY CONCEPTS

- Somatoform disorders as a diagnosis has been eliminated from the DSM-5 and reconceptualized with the category of SSDs.
- The patient with functional neurological symptom disorder, what was termed conversion disorder previously, requires a careful and complete neurological examination. Rather than miss the subtle presentation of a neurological disorder, it may be appropriate to perform imaging and obtain neurological and psychiatric consultation. Do not assume that the patient with neurological deficits has a psychiatric disorder.
- Success with the SSD patient depends on establishing rapport with the patient and legitimizing their complaints to avoid a dysfunctional physician-patient interaction.
- Avoid telling the SSD patient “it is all in your head” or “there is nothing wrong with you.” These patients are very sensitive to the idea that their suffering is being dismissed.
- A useful approach is to discuss recent stressors with the patient and suggest to them that at times our bodies can be smarter than we are, telling us with physical symptoms that we need assistance. This approach alone may transform the ED visit from a standoff between physician and patient, to a grateful patient who develops greater insight and is amenable to referral.
- Avoid prescribing unnecessary or addictive medications to the SSD patient.
- If you suspect a diagnosis of SSD, refer the patient to primary care or psychiatry for further evaluation and treatment.
- Evaluate and refer appropriately for any concurrent anxiety or depression; psychiatric consultation is needed in the setting of acute decompensation.
- Patients with SSD are best cared for by establishing an ongoing relationship with a primary care provider, and it is appropriate to stress this with the SSD patient.

CHAPTER 103: QUESTIONS & ANSWERS

103.1. Which of the following is most likely to occur from ordering of excessive diagnostic tests in patients with a somatic symptom disorder?
   A. A conclusive diagnosis
   B. An improved physician-patient relationship
   C. Morbidity from repeated diagnostic tests
   D. Patients who are reassured by excessive testing
   E. The exclusion of organic disease with absolute certainty

**Answer:** C. Repeated diagnostic testing in somatizing patients not only leads to excessive use of health care services and iatrogenic harm but, in addition, does not lead to increased patient satisfaction, decreased suffering, or improved physician-patient relationship. The most reasonable approach to the patient with a potential diagnosis of somatic symptom disorder is a rational search for biomedical causes along with an open discussion of psychosocial issues from the start of the patient encounter.

103.2. Which of the following is more likely in patients with recent-onset somatic disorder compared with patients with long-term somatic disorder?
   A. Anxiety
   B. Depression
   C. Grief reaction
   D. All of the above

**Answer:** D. Patients who present with the recent onset of somatization are more likely to have an acute psychological stressor that they are either unwilling or unable to directly report and may instead use somatic symptoms to legitimize their presentation to the emergency department. The diagnosis of somatization disorder requires multiple, recurrent, unexplained symptoms rather than an acute complaint in a single visit.

103.3. Which of the following approaches is the most appropriate for diagnosis and treatment of somatic symptom disorder?
   A. Confront the patient and explain that there is nothing “wrong.”
   B. Order multiple diagnostic tests.
   C. Proceed with the assumption that the patient is malingering.
   D. Refer the patient to insight-oriented psychotherapy.
   E. Use effective and appropriate communication skills.

**Answer:** E. Effective and appropriate communication skills are key to the diagnosis and treatment of patients with a somatic symptom disorder. These patients do not meet the criteria for factitious disorder or malingering. Patients with a somatic symptom disorder have reduced symptoms and improved functioning when the physician does not attempt to minimize the experience of symptoms with comments such as “It is all in your head.” In addition, these patients appear to derive very little benefit from insight-oriented psychotherapy; rather, they will maintain improved functional health status and require fewer physician visits if they have an ongoing and trust-based relationship with the primary care physician.

103.4. A patient presents with the sudden onset of blindness, which cannot be explained medically. Which of the following is the most likely to be true?
   A. The condition is under the patient’s voluntary control.
   B. The patient is more likely to have preexisting eye disease.
   C. The patient is unlikely to have any comorbid diagnosis, such as mood disorder, panic disorder, or post-traumatic stress disorder.
   D. The presentation represents the patient’s own perception of neurologic illness.

**Answer:** D. Patients with a functional neurological disorder may present to the physician with what they believe represents a neurologic illness. They are likely to have an underlying comorbid diagnosis, such as mood disorder, panic disorder, or post-traumatic stress disorder. Interestingly, the presentation, such as blindness or paralysis of the lower extremities, is not under the patient’s voluntary control.

103.5. Which of the following statements regarding somatization disorder is true?
   A. A specific symptom may point to the diagnosis.
   B. More symptoms correlate with a higher likelihood of psychiatric illness.
   C. The symptoms may be feigned or voluntary.
   D. There is no direct association with anxiety.
   E. There is no direct association with depression.

**Answer:** B. Women with more than five symptoms and men with more than three symptoms have a much higher likelihood of psychiatric illness. The symptom complaints are neither feigned nor voluntary but, rather, more a manifestation of some sort of distress. There is an association with both depression and anxiety. It is the multiplicity rather than the specificity of symptoms that suggests the diagnosis.

103.6. Which of the following statements regarding chronic pain syndrome (pain disorder) is true?
   A. Chronic pain behavior patterns are fixed after 2 weeks.
   B. It may be intentionally feigned.
   C. It often follows a specific traumatic event.

**Answer:** B. Women with more than five symptoms and men with more than three symptoms have a much higher likelihood of psychiatric illness. The symptom complaints are neither feigned nor voluntary but, rather, more a manifestation of some sort of distress. There is an association with both depression and anxiety. It is the multiplicity rather than the specificity of symptoms that suggests the diagnosis.
D. The pain is limited to the single organ system or injury.
E. There is typically a pathophysiologic explanation for the pain.

**Answer:** C. Most cases of chronic pain follow a specific traumatic or industrial event. It is not intentionally feigned, usually involves more than one organ system, and limits function, and the degree of pain or incapacitation cannot be explained medically. Pain behaviors are typically fixed at 3 months, and failure to improve or to return to normal function at 2 weeks should raise concerns and prompt review.
Factitious Disorders and Malingering

Jag S. Heer

CHAPTER 104

PRINCIPLES

Patients may present to the emergency department (ED) with symptoms that are simulated or intentionally produced. The reasons that cause this behavior define two distinct varieties: factitious disorders and malingering.

**Factitious disorders** are characterized by symptoms or signs that are intentionally produced or feigned by the patient in the absence of apparent external incentives. Factitious disorders have been present throughout history. In the second century, Galen described Roman patients inducing and feigning vomiting and rectal bleeding. Hector Gavin sought to categorize this behavior in 1834. These patients constitute approximately 1% of general psychiatric referrals, but this percentage is lower than that seen in emergency medicine because these patients rarely accept psychiatric treatment. Of patients referred to infectious disease specialists for a fever of unknown origin, 9.3% of the disorders are factitious. Between 5% and 20% of patients observed in epilepsy clinics have psychogenic seizures, and the number reaches 44% in some primary care settings. Among patients submitting kidney stones for analysis, up to 3.5% are fraudulent.

The *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) classifies factitious disorders into two types: factitious disorder imposed on self (FDIS) and factitious disorder imposed on another (FDIA).

Munchausen syndrome, the most dramatic and exasperating of the FDIS, was originally described in 1951. This fortunately rare syndrome takes its name from Baron Karl F. von Munchhausen (1720 to 1797), a revered German military officer and noted raconteur who had his embellished life stories stolen and parodied in a 1785 pamphlet. The diagnosis applies to only 10% to 20% of patients with factitious disorders. Other names applied include the “hospital hobo syndrome” (patients wander from hospital to hospital seeking admission), peregrinating (wandering) problem patients, hospital addict, polysurgical addiction, and hospital vagrant.

FDIA, an especially pernicious variant that involves the simulation or production of factitious disease in children by a parent or caregiver, was first described in 1977. There are approximately 1200 estimated new cases of FDIA per year in the United States. The condition excludes straightforward physical abuse or neglect and simple failure to thrive; mere lying to cover up physical abuse is not FDIA. The key discriminator is motive: the mother is making the child ill so that she can vicariously assume the sick role with all its benefits. The mortality rate from FDIS is 9% to 31%. Children who die are generally younger than 3 years old, and the most frequent causes of death are suffocation and poisoning. Permanent disfigurement or permanent impairment of function resulting directly from induced disease or indirectly from invasive procedures, multiple medications, or major surgery occurs in at least 8% of these children. Other names applied include Polle’s syndrome (Polle was a child of Baron Munchhausen who died mysteriously), factitious disorder by proxy, pediatric condition falsification, Munchausen syndrome by proxy, and Meadow’s syndrome.

Malingering is the simulation of disease by the intentional production of false or grossly exaggerated physical or psychological symptoms, motivated by external incentives, such as avoidance of military conscription or duty, avoidance of work, obtainment of financial compensation, evasion of criminal prosecution, obtainment of drugs, gaining of hospital admission (for the purpose of obtaining free room and board), or securing of better living conditions. The most common goal among such “patients” presenting to the ED is to obtain drugs, whereas in the office or clinic the gain is more commonly insurance payments or industrial injury settlements. The true incidence of malingering is difficult to gauge because of underreporting, but estimates include a 1% incidence among mental health patients in civilian clinical practice, 5% in the military, and as high as 10% to 20% among patients presenting in a litigious context. The most likely conditions to be feigned are mild head injury, fibromyalgia, chronic fatigue syndrome, and chronic pain.

CLINICAL FEATURES

**Factitious Disorders**

**Factitious Disorders Imposed on Self**

The diagnosis of FDIS depends on specific criteria (Box 104.1). With a factitious disorder, the production of symptoms and signs is compulsive; the patient is unable to refrain from the behavior even when its risks are known. The behavior is voluntary only in the sense that it is deliberate and purposeful (intentional) but not in the sense that the acts can be fully controlled. The underlying motivation for producing these deceptions, securing the sick role, is primarily unconscious. Individuals who readily admit that they have produced their own injuries (eg, self-mutilation) are not included in the category of factitious disorders. Presentations may be acute, in response to an identifiable recent psychosocial stress (termination of romantic relationship, threats to self-esteem), or a chronic life pattern, reflective of the way in which the person deals with life in general. The symptoms involved may be either psychological or physical.

**Psychological Symptoms.** This disorder is the intentional production or feigning of psychological (often psychotic) symptoms suggestive of a mental disorder. Stimulants may be used to induce restlessness or insomnia; hallucinogens, to create altered levels of consciousness; and hypnotics, to produce lethargy. This psychological factitious condition is less common than factitious disorders with physical symptoms and is almost always superimposed on a severe personality disorder.

**Physical Symptoms.** The intentional production of physical symptoms may take the form of fabricating of symptoms without signs (eg, feigning abdominal pain), simulation of signs suggesting illness (eg, fraudulent pyuria, induced anemia), self-inflicted conditions (eg, the production of abscesses by injection of contaminated material under the skin), or genuine complications...
BOX 104.1

**DSM-5 Criteria for the Diagnosis of Factitious Disorder Imposed on Self**

1. Falsification of psychological or physical signs or symptoms, or induction of disease or injury associated with identified deception.
2. The individual presents to others as injured, ill, or impaired.
3. The deceptive behavior is apparent even in the absence of external incentives.
4. The behavior is not better explained by another mental disorder.

Munchausen Syndrome. The uncommon patient with true Munchausen syndrome has a prolonged pattern of “medical imposture,” usually years in duration. The behavior usually begins before 20 years old and is diagnosed between 35 and 39 years old. Twice as many men as women are affected. 4,13,16 Patients’ entire adult lives may consist of trying to gain admission to hospitals and then steadfastly resisting discharge. Their career of imposture usually lasts about 9 years but has continued unabated for as long as 50 years. 13 The quest for repeated hospitalizations often takes these patients to numerous and widespread cities, states, and countries. 12

These individuals see themselves as important people, or at least related to such persons, and their life events are depicted as exceptional. 16 They possess extensive knowledge of medical terminology. There is frequently a history of genuine disease, and the individual may exhibit objective physical findings. 16

The symptoms presented are “limited only by the person’s medical knowledge, sophistication, and imagination.” 12 The alleged illnesses involved have been termed *dilemma diagnoses* in that investigators rarely can totally rule out the disorder, clarify the cause, or prove that it did not exist at one time. 1 Common presentations are those that most reliably result in admission to the hospital, such as abdominal pain, self-injection of a foreign substance, febrile urine, bleeding disorders, hemoptysis, paroxysmal headaches, seizures, shortness of breath, asthma with respiratory failure, chronic pain, acute cardiovascular symptoms (eg, chest pain, induced hypertension and syncope), renal colic and spurious urolithiasis, fever of unknown origin (hyperpyrexia fictamentica), profound hypoglycemia, and coma with anisocoria. 13 Some self-induced conditions are highly injurious or even lethal. 19

The patient usually presents during evenings or on weekends so as to minimize accessibility to psychiatric consultants, personal physicians, and past medical records. 10 In teaching institutions, these patients often present in July, shortly after the change in resident house officers. 10 They relate their history in a precise, dramatic, even intriguing fashion, embellished with flourishes of pathologic lying and self-aggrandizement. *Pseudologia fantastica*, or pathologic lying, is a distinctive peculiarity of these patients. In a chronic, often lifelong behavior pattern, the patient typically takes a central and heroic role in these tales, which may function as a way to act out fantasy. 12 The history quickly becomes vague and inconsistent, however, when the patient is questioned in detail about medical contacts. 1 Attempts to manage the complaint on an outpatient basis are adamantly resisted. 15 Once admitted, the patient initially appeals to the physician’s qualities of nurturance and omnipotence, lavishing praise on the caregivers. Behavior rapidly evolves, however, as the patient creates havoc on the ward by insisting on excessive attention while ignoring both hospital rules and the prescribed therapeutic regimen. 13 When the hoax is uncovered and the patient confronted, fear of rejection abruptly changes into rage against the treating physician, closely followed by departure from the hospital against medical advice. 14

Factitious Disorder Imposed on Another

The diagnosis of FDIA depends on specific criteria (Box 104.2). 2 The presenting complaints typically evade definitive diagnosis and are refractory to conventional therapy for no apparent reason. 19 The symptoms are usually more than five in number, presented in a confused picture; they are unusual or serious and, by design, unverifiable. They invariably occur when the mother is alone with the child or otherwise unobserved. 12 In 72% to 95% of cases, simulation, or production of illness occurs while the victim is hospitalized. 31,12,14

Simulated illness, faked by the mother without producing direct harm to the child (eg, the addition of blood to a urine...
specimen), is present in 25% of cases. Produced illness, which the mother actually inflicts on the child (eg, the injection of feces into an intravenous line), is found in 50% of cases. Both simulated and produced illnesses are found in 25% of cases.11-15

FDIA most commonly arises with factitious bleeding, seizures, central nervous system (CNS) depression, apnea, diarrhea, vomiting, fever, and rash.4 Reported techniques of simulation or production of disease include administration of drugs or toxins (eg, chronic arsenic poisoning, ipecac, warfarin, phenolphthalein, hydrocarbons, salt, imipramine, laxatives, CNS depressants), caustics applied to the skin, and nasal aspiration of cooking oil.11,13,18 Techniques of asphyxiation include (1) covering the mouth or nose with one or both hands, a cloth, or plastic film, and (2) inserting the fingers into the back of the mouth. In such instances, even struggling infants may sustain no cutaneous markings.19 Cases involving seizures are common and may involve third-party witnesses. On personal questioning, however, these witnesses frequently deny the occurrence of seizure activity.6,11,14

Perpetrator Characteristics. Ninety-eight percent of perpetrators are biologic mothers who come from all socioeconomic groups.11-14 Many have a background in health professions or social work, or a past history of psychiatric treatment, marital problems, or suicide attempts.11-15 Depression, anxiety, and somatization are common, but frank psychotic behavior by the mother is atypical.11 Perpetrators of FDIA have an inherent skill in manipulating health care workers and child protection services.13 They are pleasant, socially adept, cooperative, and appreciative of good medical care. They often display a peculiar eagerness to have invasive procedures performed on their child. They often prefer to stay in the hospital with their child, cultivate unusually close relationships with hospital staff, and thrive on staff attention.11-14 This affable relationship with the medical team rapidly changes to excessive anger and denial when the perpetrator is confronted with suspicions.12,13

Most of these mothers have had an abusive experience early in life, and they use the health care system as a means to satisfy personal nurturing demands.3,22 They often cannot distinguish their needs from the child’s and satisfy their own needs first. They derive a sense of purpose from the medical and nursing attention gained when their children are in the hospital.11-13 Alternatively, the behavior may enable the mothers to escape from their own physical or psychological illnesses, marital difficulties, or social problems.13

Victim Characteristics. Victims of FDIA are equally male and female children. The mean age at diagnosis is 40 months, and the mean duration from the onset of signs and symptoms to diagnosis is 15 months.11-13 A known physical illness that explains part of the symptoms is common among these children.13 Most have a history of significant failure to thrive and have been hospitalized in more than one institution. Delays in many areas of performance and learning, difficulty with family relationships, attention deficit disorder, or clinical depression may coexist.13 Some of these victims may have factitious disorder later in life. Elders may also be victims of FDIA, although this is uncommon.10

Approach to Diagnosis. Suspected FDIA requires a detailed description of the event or illness and a search for caregiver witnesses, who should be interviewed personally. Although it is essential to see the child when the symptoms are present, the parents show great ingenuity at frustrating this effort.12,23 Additional history of unusual illness in siblings and parents should be sought. Child victims who are verbal should be interviewed in private about foods, medicines, and their recollection of the symptoms or events. Prior medical records of the victim and, if possible, the siblings should be examined, although parents may impede such data gathering.

The major obstacle to early discovery of FDIA is its omission from the differential diagnosis. When it is considered, the diagnosis is generally made easily and quickly.11-13 A suspected diagnosis may be confirmed through separation of the parent from the child or individual (with consequent cessation of symptoms), covert video surveillance during hospitalization, or toxicologic screens.16 In the majority of cases, the caregiver attempts to induce episodes surreptitiously while in the hospital, often during the first day of admission.11-15

Malingering

Malingering is frequently found in association with antisocial personality disorder. On questioning, malingers are vague about prior hospitalizations or treatments. The physicians who previously treated them are usually unavailable. At times, malingerers may be careless about their symptoms and abandon them when they believe no one is watching.8 In some “patients,” such as those seeking drugs, homeless persons seeking hospital admission on a cold night, or prisoners wanting a holiday from incarceration, the secondary gain may be clear. In other persons, the external incentive may be obscure.

In contrast to the person with factitious disorders, the malingerer prefers counterfeit mental illness, because it is objectively difficult to verify or to disprove. Amnesia is the most common psychological presentation, followed by paranoia, morbid depression, suicidal ideation, and psychosis.13 Malingering should be strongly suspected with any combination of certain factors (Box 104.3).2 A definitive diagnosis of malingering is rare and can be established only with the patient’s confession.7 Because malingering constitutes criminal behavior, documentation of this diagnosis should be made with care.13 In the absence of proof of wrongdoing, it is best to assume that the

**Box 104.2**

**DSM-5 Criteria for the Diagnosis of Factitious Disorder Imposed on Another**

1. Falsification of psychological or physical signs or symptoms, or induction of disease or injury in another, associated with identified deception.
2. The individual presents another individual (victim) to others as injured, ill, or impaired.
3. The deceptive behavior is apparent even in the absence of external incentives.
4. The behavior is not better explained by another mental disorder.

**Box 104.3**

**Characteristics of Malingering**

1. Medico/legal context of the presentation (eg, the patient was referred by his or her attorney)
2. Marked discrepancy between the person’s claimed stress or disability and objective findings
3. Poor cooperation during the diagnostic evaluation or poor compliance with previously prescribed treatment regimens
4. The person exhibits or has a history of antisocial behavior
patient is not a malingerer but rather a common somatizer. Maligners who pursue drugs may report an unusually large number of drug allergies to persuade the physician to prescribe their drug of choice or simply insist on a specific drug (eg, meperidine [Demerol] or hydromorphone [Dilaudid]). Unfortunately, the Internet offers a wide availability of quality medical advice on how to convincingly feign pain and disability.

**DIFFERENTIAL DIAGNOSIS**

The most important diagnoses to be excluded are genuine medical and psychiatric conditions that might account for the presenting symptoms. Patients with conversion disorder, somatic disorder, delusional disorder of somatic type, and borderline personality disorder can present with symptoms similar to FDIS. The differences can be subtle and psychiatric consultation or referral is indicated.

Patients with factitious disorders are distinguished from malingers because their desired hospitalization or surgery seems to offer no secondary gain other than to play the sick role. The clinical presentation of the majority of patients with factitious disorders, unlike those with Munchausen syndrome, is relatively subtle and convincing. The complaints are generally chronic in nature rather than emergent and precipitous, and there are no obvious associated behavioral aberrations. The chronicity of malingering is usually less than that associated with factitious disorder, and malingers are more reluctant to accept expensive, possibly painful, or dangerous tests or surgery.

**MANAGEMENT**

**Factitious Disorders**

Treatment options for factitious disorders depend on the patient's characteristics. Although it is challenging, management of common forms of factitious disorder can be more rewarding, especially with adolescents, than management of Munchausen syndrome. The prognosis is more favorable for cases with an underlying depression than for those associated with borderline personalities. The best approach to patients with factitious disorder, other than Munchausen syndrome and FDIA, is controversial. Direct non-accusatory confrontation has been advocated as "the foundation of effective management" when it is coupled with the assurance that the patient's condition has been adequately evaluated. This may be the first step in the acceptance of outpatient therapy.

Others point out that confrontation is ineffective in most patients and may even be counterproductive in that it threatens to undermine a needed psychological defense. Enforced recognition of external objective reality, while simultaneously disallowing the patient's subjective experience, may generate even more dysfunction directed at legitimizing and maintaining symptoms and may even place the patient at risk for suicide. Some patients may relinquish this defense if they feel safe in doing so and may abandon a claim to disease if some face-saving option is offered. This approach, termed the therapeutic double bind or contingency management, involves informing the patient that a factitious disorder may exist. The patient is further told that failure to respond fully to medical care would constitute conclusive evidence that the patient's problem is not organic but rather psychiatric. The problem is therefore reframed or redefined in such a way that (1) symptoms and their resolution are both legitimized and (2) the patient has little choice but to accept and respond to a proposed course of action or seek care elsewhere.

Individuals with Munchausen syndrome typically demonstrate overt sociopathic traits or a borderline personality disorder and are demanding and manipulative, especially regarding analgesics. They have been described as "essentially untreatable," and successful management of this condition is, in fact, considered reportable. Early confrontation or limit setting, especially regarding drug use, is advocated. Although Munchausen patients typically do not want to be examined extensively, a thorough physical examination should be performed to rule out physical disease.

FDIA constitutes a form of child (or elder) abuse, and appropriate action to protect the victim, including notification of state social service agencies, should take immediate priority. If available, a pediatrician who has expertise in child abuse should assess the case. When the diagnosis has been established and the parents have been confronted, psychiatric care should be made immediately available to the parents because maternal suicide is a significant risk.

**Malingering**

Maligners do not want to be treated. Because they are "gaming the system" for personal advantage, the last thing they want is an accurate identification of their behavior and appropriate intervention. The emergency clinician should maintain clinical neutrality, offering the reassurance that the symptoms and examination are not consistent with any serious disease.

Some authors have characterized patients' use of medical resources under false pretenses as criminal behavior, and several states have enacted legislation against the fraudulent acquisition of medical services with successful prosecution of such behavior. Conversely, patients with factitious disorders can and do sue. In dealing with such patients, it is advisable to involve hospital administration and risk management. Clandestine searches are inadvisable, and respect for the patient's confidentiality should be maintained.

**DISPOSITION**

Patients suspected of having a factitious disorder should be referred for primary care follow-up, and if it is acceptable to the patient, psychiatric referral should also be arranged. Referral to other medical specialists or hospitalization should be avoided when possible.

The manner of presentation and the unavailability of past medical history often allow patients with Munchausen syndrome to achieve hospital admission. If the patient is discharged from the ED, outpatient primary care follow-up and psychiatric referral should be offered, although both are likely to be refused.

Because perpetrators of FDIA typically induce symptomatic episodes soon after hospitalization, admission of the victims (children or elders) without taking appropriate precautions may actually place them at increased risk. Visits by the suspected perpetrator should be closely supervised, and no food, drink, or medicines should be brought in by the family. Protective services should be notified. Out-of-home placement of children in established cases of FDIA is advisable, and the best outcomes are seen among children taken into long-term care at an early age without access to their mother. Children allowed to return home face a high rate of repeat abuse. In 20% of reported deaths, the parents had been confronted and the child sent home to them, subsequently to die.

After courteous but assertive reassurance, suspected maligners should be offered primary care follow-up if the symptoms do not resolve. These individuals may become threatening when they are either denied treatment or overtly confronted.
### KEY CONCEPTS

- Patients who have consciously synthesized symptoms and signs may be divided into two broad diagnostic categories: (1) those with obvious secondary gain (malingering), who control their actions, and (2) those with a motivation of achieving the sick role (factitious disorders), who cannot control their actions.
- The initial management of patients suspected of fabricating disease should include a caring, nonjudgmental attitude and a search for objective clinical evidence of treatable medical or psychiatric illness.
- Review of old medical records and interview of family members are often helpful.
- Unnecessary tests, medications, and hospitalizations should be avoided in the absence of objective evidence of a medical or psychiatric disease, and patients should be referred for ongoing primary care.
- In cases of suspected FDIA involving children or elders, protection of the victim takes first priority.

CHAPTER 104: QUESTIONS & ANSWERS

104.1. Which of the following statements regarding factitious disorder is true?
   A. It involves voluntary and controllable symptom production.
   B. Patients are generally well educated and otherwise responsible.
   C. Presentations are not related to an identifiable event.
   D. The symptoms produced are always physical ones.
   E. The underlying motivation is a conscious one.

   **Answer:** B. Many such patients are actually employed in the health care industry. The act of producing symptoms is voluntary but not controllable and derives from a subconscious motivation. Presentations are very often related to a “traumatic” event, such as a breakup. Produced symptoms may be physical (eg, hematuria) or psychological. The typical patient is an unmarried female younger than 40 years. Despite undergoing invasive procedures and associated hardships, these patients seek more medical care and hospitalization.

104.2. Which of the following statements concerning Munchausen syndrome by proxy is true?
   A. A known physical illness in the child is common.
   B. Most maternal perpetrators are demanding, uncooperative, and socially inept.
   C. Most maternal perpetrators are not a biologic parent.
   D. Psychosis is common in the maternal perpetrator.
   E. The mean age of victim diagnosis is 7 to 9 years.

   **Answer:** A. Victim children often have a legitimate illness. Mean age at diagnosis is 40 months. Most have a history of failure to thrive and multiple hospitalizations. The perpetrator receives some personal fulfillment from the care and attention of the hospital staff, which is often admiration for her persistence, willingness to sacrifice and patience, and she is typically pleasant, medically savvy, and socially skilled. Invasive procedures on the child are often welcomed. Although psychosis is very unusual in the parent, depression, anxiety, and somatization are typical in the perpetrator.

104.3. A 2-year-old female presents with new onset seizures. Her past medical history is unremarkable. Laboratory evaluation reveals blood glucose of 20 mg/dL. The patient’s mother denies a family history of diabetes or having medications the child might have ingested at home. She works as a nurse at a local hospital and has been with the child all day. The child’s symptoms improve with glucose administration and a meal. Your colleague remembers evaluating the child recently for a known physical illness in action? Psychosomatics 56(6):699–614, 2015.

104.4. A prison inmate presents after falling from the top bunk in his cell. He is complaining of lower lumbar pain and states he is unable to move or feel his lower extremities from his waist down. On physical examination, lower extremity reflexes are present but the patient denies feeling pain or light touch sensation below the waist. Lumbar spine CT and MRI are negative. Which of the following conditions is most likely?
   A. Cord contusion
   B. Factitious disorder
   C. Malingering
   D. Munchausen syndrome

   **Answer:** C. Malingering is the intentional symptom production for secondary gain. There is a marked discrepancy between claimed disability and the actual objective findings. Confessions and proof are rare.
CHAPTER 105

Suicide

Marian E. Betz | Jeffrey M. Caterino

PRINCIPLES

Background

Emergency clinicians care for large numbers of patients with suicidal ideation and self-harm behaviors. Two facts are especially important to remember in the care of suicidal patients. First, many suicide attempts occur during an acute crisis, such as a personal loss or the exacerbation of an underlying psychiatric disorder. This acute crisis is usually time limited and may be resolvable or treatable. Second, suicidal patients are usually ambivalent about dying and grateful for help. An empathetic, patient-centered, and evidence-based approach offers the opportunity to save lives.

Epidemiology

In 2011, suicide was the fourth leading cause of death in the United States for adults between 18 and 65 years old. There are more than one million suicide attempts and 41,000 suicide deaths in the United States, and rates are rising. Between 1999 and 2010, the age-adjusted suicide rate among 35 to 64 year olds increased 28.4%. In the United States, there are over 800,000 visits to emergency departments (EDs) each year for self-inflicted injuries. Many patients evaluated for suicidality are discharged; in 2008, only half of ED visits for suicide attempts resulted in hospitalization.

Suicide rates vary with age and are highest in elders, particularly older white men (Fig. 105.1 and Table 105.1). Whites and Native Americans have higher rates of suicide than African Americans, Hispanics, or Asians. Women attempt suicide three to four times more often than men, whereas men are three to four times more likely to die after an attempt (due to use of more lethal methods) and have higher suicide death rates in all age groups (see Fig. 105.1). Both pregnancy and motherhood seem to protect against suicide, except in cases of postpartum depression. Sexual orientation is also associated with suicide risk because youth identifying as lesbian, gay, or bisexual have increased risk for suicidal ideation and attempts. Suicide also varies geographically, with higher rates in the Western United States, rural areas, at higher elevations, and in areas with higher levels of firearm ownership. Among military personnel, suicide risk is increased in males and those with psychiatric history, alcohol abuse, or previous deployment. In 2012, suicide surpassed war as the leading cause of death in the military.

Risk Factors

There are many factors associated with an increased risk of suicide (see Table 105.1), although it is important to recognize that some of these have stronger associations than others. Some risk factors are dynamic, whereas others are static; thus an individual patient’s risk may vary over time, but helping someone at a current low risk of suicide may prevent future escalation to high risk.

Self-Harm

A prior history of non-suicidal self-harm or suicide attempt, even in the remote past, is an important risk factor (see Table 105.1). Because 10% to 15% of suicide attempters will ultimately die by suicide, prior suicide attempt is one of the most important predictors of a future attempt. At the same time, up to 80% of suicide completers have no prior history of attempts and die on the first known attempt.

Mental Illness

The presence of an affective disorder, especially major depression, is also a strong independent risk factor for suicide. There are increased rates of suicide in patients with schizophrenia, bipolar disorder, borderline personality traits or disorder, anxiety disorder, and post-traumatic stress disorder. Overall, the risk of suicide in patients with mental illness increases with the presence of prior attempts, recent psychiatric hospitalization, male gender, more severe symptoms, hopelessness, comorbid psychiatric disorders, use of alcohol or drugs, and family history of suicide. The presence of comorbid depression in the setting of other mental illness is a particularly strong factor. In patients hospitalized for psychiatric disorders, the risk for suicide is greatest in the first month after discharge, especially in the first week. Some patients, particularly children and adolescents, may have increased suicidal thoughts or attempts soon after the initiation of antidepressant medications. This may be due to the “mobilization of energy” theory, which suggests profoundly depressed patients have the energy to attempt suicide only as their condition improves with treatment. The clinician should recognize the time period around initiation of antidepressant therapy as one requiring heightened scrutiny for suicidal thoughts or behaviors.

Alcohol and Substance Abuse

Both chronic and acute alcohol abuse are associated with suicide. Patients with chronic alcohol use have over nine times the risk of completed suicide. Alcoholics who die from suicide usually have multiple risk factors, including major depression, unemployment, medical illness, and interpersonal loss. Acute alcohol use is associated with increased risk of suicide in both those with and without chronic alcohol abuse, and this risk persists for 24 to 48 hours after drinking, particularly heavy drinking. This effect is largest among younger adults and is more often associated with violent means of suicide (eg, firearms or hanging). Substance abuse is associated with increased frequency, repetitiveness, and lethality in suicide attempts. Illicit substances are often detected at the time of suicide; of all suicides in 16 states in 2010, 33% tested positive.
Adolescence

Suicide is the third leading cause of death in people 15 to 24 years old. In a national survey of high school students in the United States, in the previous year 17% had had serious thoughts of suicide, 13% had made a suicide plan, and 8% had made a suicide attempt. Similar to the adult population, adolescent girls are more likely to attempt suicide, whereas boys are more likely to die by suicide. Most adolescents who die by suicide have made previous suicide threats. Suicide risk factors in adolescents and young adults have been identified (Table 105.2). History of suicide attempt and of non-suicidal self-harm are particularly strong risk factors.

Older Age

Suicide rates are particularly high in elders, especially older white men, who account for over 80% of suicide deaths among older adults (see Fig. 105.1). Older adults with suicide attempts are more likely to die because of the use of more lethal methods, more advanced planning, and a lower likelihood of asking for help, having warnings recognized by others, or having a successful crisis intervention. Suicide rates among the baby boomer generational cohort appear to be higher than in previous generations, highlighting the need for suicide prevention efforts targeted toward this group. Among older adults, depression is the strongest risk factor for suicide, with a prevalence of up to 80% among older suicide decedents. Additional important risk factors in elders include cognitive dysfunction, decreased functional ability, bereavement or other stressful life events, social isolation, and loneliness.

Chronic Illness

Many chronic medical illnesses are associated with increased risk of suicide, particularly those with chronic pain or impairment in activities of daily living. Infection with human immunodeficiency virus (HIV) or presence of the acquired immunodeficiency syndrome (AIDS) remains associated with increased risk of suicide, both due to an increased incidence of major depression and to increased rates of cognitive dysfunction in older patients with HIV/AIDS.

Other Risk Factors

Financial stress can increase the risk of suicide, with both male and female suicide rates increased in times of recession and increasing unemployment. Homeless people with mental

| Sociocultural | Participation in Goth subculture |

---

illness are at high risk for suicide, which is in part because of the high prevalence of other suicide risk factors. Recent incarceration is also a suicide risk factor. The risk of suicide in recently released prisoners approaches that of recently discharged psychiatric patients.

**Methods of Suicide**

Firearms account for more than half (52%) of completed suicides, followed by hanging or suffocation (25%), and poisoning (16%). Firearms are the most common method of completed suicide among males (58%), but poisonings are more common among women (37% poisoning versus 31% firearms). In one large study, poisoning with drugs accounted for 74% of acts but only 14% of fatalities; firearms and hanging accounted for only 10% of acts but 67% of fatalities. There is a well-established relationship between the presence of a firearm in the home and higher rates of suicide. Compared to households without, households with a firearm have increased rates of suicide but similar rates of mental disorders, substance abuse, suicidal ideation, and suicidal planning. This suggests the presence of a firearm has an independent effect on the risk of death by suicide because of the associated high case fatality rate of firearm suicide.

Poisoning accounts for over two-thirds of ED visits for suicide attempt or self-harm. Prescription drugs are much more commonly associated with these visits than are illicit drugs; among prescription drugs, anxiolytics, sedatives, and hypnotics are most commonly present (41%), followed by antidepressants (20%).

**Pathophysiology**

The etiology of suicide is a complex mix of social, genetic, and psychological factors. Current research suggests a biologic basis for depression and suicide involving the serotonin systems. People who attempt suicide have altered serotonin receptor function and low serotonin levels. The genetic basis of suicide is not clearly understood, but several genes affecting the serotonin system have been implicated. Additional potential mechanisms include excessive noradrenergic neurotransmission and hyperactivity of the hypothalamic pituitary axis, but studies are conflicting. Low serum and cerebrospinal fluid (CSF) levels of brain-derived neurotrophic factor, a neurotrophic factor that regulates neuronal development, function, and survival, have also been associated with suicide.

**CLINICAL FEATURES**

The potential for suicide should be considered in patients with suicide risk factors (see Table 105.1) and in patients who “unintentionally” overdose or have had “accidental” gunshot wounds, lacerated wrists, automobile crashes, or falls from heights. Providers should also consider suicidal thoughts or behavior in patients who present to the ED repeatedly because of noncompliance with treatment of their medical disorders. Patients who are not overtly depressed or suicidal but who exhibit one or more of these high-risk presentations previously described should be assessed in a sympathetic but direct manner using a “graduated” approach. Rapport can first be established during a general medical and psychiatric history, with an evaluation of the patient’s home, work, and social situation, followed by specific questions about the signs and symptoms of depression and about suicidal thoughts. Such questioning does not place the concept of suicide into the mind of someone who has not been considering it.

The approach described earlier can be described as indicated screening (questioning of those with “red flag” acute risk factors for suicide, such as psychosocial stressors). A more systematic screening approach would be selective screening (questioning of all patients in high-risk groups, such as those with chronic risk factors for suicide like prior attempts or mental illness). Universal screening for suicidal risk involves questioning all patients about suicidal thoughts or behaviors. Advocates of universal screening argue that other approaches miss patients with “occult” suicidality; research suggests that approximately 10% of all ED patients have recent suicidal ideation or behaviors, and 40% of suicide victims have visited an ED within the prior year. A National Patient Safety Goal (15.01.01) from the Joint Commission requires “general hospitals treating individuals for emotional or behavioral disorders, to identify patients at risk for suicide.” This goal can be met by targeted or universal screening. For ideal functioning, any screening program should be integrated into electronic medical records and current work flow to optimize efficiency and provider uptake.

**DIFFERENTIAL DIAGNOSIS**

Self-directed violence (SDV) encompasses both suicidal and non-suicidal self-injurious behaviors. Non-suicidal SDV “deliberately results in injury or the potential for injury to oneself” in the absence of suicidal intent (eg, cutting or burning). Suicidal ideation refers to thoughts of causing one’s own death, with or without a specific plan. Suicidal behavior is any behavior with the intent to end one’s life. A suicide attempt is a “non-fatally self-directed potentially injurious behavior with any intent to die as a result of the behavior.” An interrupted suicide attempt is a suicide attempt aborted by the individual or another person. Occult suicide is suicidal thoughts or behaviors not admitted to by the patient, such as self-destructive acts disguised as accidents (eg, an intoxicated, depressed driver who crashes his car). Suicide by cop is where a suicidal individual intentionally provokes a police officer by orchestrating a situation in which the officer is forced to shoot in self-defense or to protect other civilians. Terms to avoid (because of the suggested value judgment) include committed or successful suicide, suicidal gesture, manipulative act, and suicide threat.

**DIAGNOSTIC TESTING**

Emergency clinicians are often asked to provide medical clearance of patients with psychiatric emergencies. However, the preferred term is focused medical assessment; a negative focused medical assessment does not indicate an absence of medical problems but rather that such problems can be addressed on a non-urgent basis. A focused assessment should be accomplished primarily through obtaining an adequate patient history and physical examination.

The history should include details about the patient’s suicidal thoughts (including onset and frequency), plans (including method, intent to act, and access to lethal means), and behaviors (including prior or recent attempts, as well as aborted or interrupted attempts). Other important points include prior medical and psychiatric conditions, prior outpatient or inpatient psychiatric care, current medications, and current drug or alcohol use (including recent use). The history should also assess symptoms suggestive of concomitant medical illness. Intoxication should not preclude taking a history, but the provider should repeat the interview when the patient is sober.

The examination should assess for evidence of drug ingestion, trauma, or associated medical illness, as well as evidence of self-harm behavior such as wrist-cutting. The patient’s cognitive status, vital signs, pupils, skin, and nervous system are helpful in detecting organic conditions, particularly toxidromes associated with common ingestions (see Chapter 139). In the case of altered mental status, the provider should determine whether the condition is caused by an organic (medical) or functional (psychiatric)

*Testing should generally be targeted to the individual patient and performed where clinically indicated, not as part of a routine screening panel.

cause (see Chapter 100). The clinician should identify medical conditions requiring acute treatment in the ED or near-future and note incidental findings requiring further outpatient management or conditions that may affect psychiatric care.

Routine, non-targeted diagnostic testing of all suicidal patients (eg, mandatory laboratory or radiographic studies) is not necessary and has not demonstrated any clinical benefit.44,56 Across several studies in both children and adults, less than 1% of patients had their disposition changed through use of testing thought to be unnecessary by the emergency clinician.54 Targeted diagnostic testing should be based on clinical grounds (Table 105.3). However, local practices vary and some mental health facilities may require routine baseline testing.

**MANAGEMENT**

Care of potentially suicidal patients requires an empathetic and patient-centered approach. Patients feel more comfortable discussing personal issues when health care personnel are friendly, nonjudgmental, and supportive.57 Providers can improve the ED experience by explaining to patients what to expect from the evaluation (eg, estimated length of wait) and attending to basic comforts (eg, food, blankets, or television).57 Trained peer specialists, when available, can also act as advocates for patients and families and may improve the experience.57,58 The use of a patient-centered approach can also enhance patient satisfaction and the likelihood of follow-up.59 Unfortunately, ED staff may be unsympathetic toward patients who attempt suicide, often because of personal beliefs or because of inadequate training, time or personnel to provide appropriate psychiatric evaluation.60 They may perceive the patient’s behavior as abusive or manipulative and may become frustrated with ineffective disposition and follow-up options. Failure to anticipate and overcome these factors can result in inadequate patient assessment and reinforce these patients’ already low self-esteem.

The first priority in managing patients is to complete a focused medical assessment to identify and treat associated medical conditions that may underlie a patient’s altered mental status or suicidal behavior. The presence of a do-not-resuscitate order in a patient with a suicide attempt raises ethical and legal dilemmas, given the debate over whether the suicide attempt resulted from a "rational" decision. Policies vary among states, and there are unfortunately no definitive guidelines for emergency care providers.61 When possible, consultation with an ethics consultant or committee or legal representation from the hospital can be helpful, but in time-sensitive conditions (eg, respiratory depression) the physician should err on the side of resuscitation. Patients with significant injury, poisoning, or other acute medical problems should be hospitalized so that their medical problems can be treated as they remain under constant observation for suicide risk and later receive the appropriate psychiatric evaluation.

**Suicide Precautions**

The ED should ensure the patient’s safety and prevent suicide attempts or self-harm within the department.62 No suicidal patient should be allowed to leave before an evaluation is completed.62 Suicidal patients who are calm and cooperative should be placed in an area where they can be safely observed by staff. Having a dedicated “sitter” or security guard to watch the patient reduces the need for restraints.63 Visiting family or friends can offer support to the patient, but they should not be used as sitters because they might not intervene if the patient attempts to leave. The use of “wander alert” bracelets, which set off an alarm if the patient crosses an established threshold, may help in monitoring.

Early in the ED stay, security or ED personnel should search suicidal patients for possible weapons, medications, and other possessions that might be used to inflict injury (eg, belts, neckties, and long shoelaces); having the patient change into a gown can facilitate this process.62 In a recent root cause analysis of 10 years of suicides and suicide attempts within Veterans Affairs hospitals or EDs, the most frequent methods were cutting (most commonly with a razor blade), hanging (most commonly from a door), and strangulation.61 The patient’s room should also be cleared of all potentially harmful objects, including medications, instruments, and glass objects. Having an official ED protocol concerning these processes is useful both to ensure patient safety and to demonstrate to patients that these are standard procedures.63

**Use of Restraints**

Mechanical and chemical restraint use is based primarily on the clinician’s judgment of the immediate risk of patient self-harm, harm to staff, or patient elopement. The clinician should first attempt other methods of de-escalation to calm agitated patients, because restraints have potential downsides. Mechanical restraints can impair rapport, be traumatic, and contribute to a depressed patient’s diminished self-esteem; chemical restraints may make subsequent psychiatric evaluation more difficult in the short term. Nevertheless, restraints may be essential and even lifesaving for uncooperative, violent, or psychotic patients. The Joint Commission and state and federal governments have stringent requirements for the use of restraints, and every ED should have a policy that conforms to these guidelines and includes a consistently-used restraint flow sheet. A timed and dated physician order and
frequent rechecks are required for all patients placed in restraints, including those in seclusion with a security watch.

**Pharmacologic Treatments**

There are no generally accepted or evidence-based protocols for drug treatment of suicidal thoughts in the ED. Antidepressants, lithium, and antipsychotics have been given to suicidal patients, but these are usually prescribed by psychiatrists and their effects occur over many weeks. ED pharmacology is usually directed to the treatment of agitation as needed, with use of a benzodiazepine or short-acting antipsychotic, such as haloperidol or olanzapine (see Chapter 189).

**Risk Assessment**

The central goals of suicide risk assessment are to identify appropriate treatment and intervention and to inform decision making about disposition (including possible psychiatric hospitalization). The likelihood of an impending suicide attempt will drive disposition: psychiatric hospitalization, emergency psychiatric consultation, or discharge with outpatient follow-up. Many suicidal patients will require a mental health consultation to assist with the process, but patients at low risk of suicide can be managed by the emergency clinician and discharged home without a formal mental health consultation. Thus, analogous to the evaluation of chest pain and other physical complaints, the emergency clinician’s role is to estimate risk, provide brief interventions, and consult specialists as indicated. All suicide risk assessments should be performed when the patient is sober. Intoxicated patients who endorse suicidal thoughts may still be at risk even if they disavow these feelings when sober. Risk assessments should also include information from “collaterals,” such as a family member or friend, because patients may give false or incomplete information. Such contacts should be made with the consent of the patient if possible. However, the clinician may make such contact without consent in cases when disclosure of protected health information is required to prevent or mitigate an imminent, serious safety threat to an individual or the public. A suicide risk assessment should consider the potential lethality of the method chosen. In particular, a plan to use a highly lethal method (like a firearm) should raise concern. However, patients may be at high risk for suicide if they believe the chosen method is likely to be lethal, even if this is unlikely from a medical standpoint (eg, ingestion of ibuprofen). Patients who plan and hide their suicide attempt may also be at higher risk of death than those who make an attempt in front of a family member or who seek medical attention. In depressed patients, an intense sense of desperation is an important predictor of suicide. Another important consideration involves the patient’s wish to live versus their wish to die; those patients with a wish to die are six times more likely to die by suicide.

A practical, step-wise approach to suicide risk assessment (Fig. 105.2) consists of brief and comprehensive steps. Brief risk assessment typically involves a short set of questions and is performed by the ED provider. No single psychological test can accurately predict suicide attempts, and most predictive scales are not designed for or suitable for use in the ED. One option is the short version of the Columbia-Suicide Severity Rating Scale, which is available for free in English and Spanish with suggested cut-points for referral and consultation. Another option is a new Decision Support Tool (Table 105.4; see Fig. 105.2), which was developed through expert consensus and identifies low risk patients who might be discharged home without psychiatric consultation. A “yes” answer to any of the Decision Support Tool’s six questions suggests the patient needs a comprehensive suicide risk assessment and consultation with a mental health specialist, if available.

A comprehensive risk assessment involves more detailed questions about a patient’s various suicide risk and protective factors and is most often performed by a mental health consultant; however, the emergency clinician still should make an independent judgment about the patient’s suicide risk. In cases where psychiatric consultation is not possible, the physician can complete a comprehensive suicide risk assessment assisted by the Suicide Assessment Five-step Evaluation and Triage (SAFE-T; Fig. 105.3) tool. The SAFE-T, which is available as a pocket card or smartphone application, guides the physician first in assessing a patient’s risk and protective factors and the specifics of suicidal

**Scoring:** ≥1 positive response suggests need for full suicide risk assessment and emergent consultation with a mental health professional (if available); see Fig. 105.2.

thoughts or plans and then combines these factors to estimate a level of risk. Some patients may prefer computer-mediated (eg, web-based) assessments to discussing sensitive topics with a stranger.

Ultimately, suicide risk assessment remains a highly individualized process integrating information about the crisis that precipitated the suicide event, the patient’s current emotional state and prior mental health history, and the presence or absence of a safe and supportive home environment. The crises that precipitate suicide attempts are often time limited, usually lasting a few hours to a few days. If a crisis has passed or can be adequately addressed, the risk of subsequent suicide is substantially diminished. Hospitalization or emergency psychiatric evaluation should be strongly considered when a patient cannot or will not participate in an evaluation of the current crisis or when the problem is unlikely to be resolved. Tools like the Decision Support Tool or SAFE-T can inform, reinforce, and justify the provider’s decision.

**Documentation**

Documentation is important due to the variable nature of suicide risk, the low rates of follow-up with outpatient care, and the difficulty of predicting imminent risk. It is especially important when restraints are necessary and when patients are either hospitalized involuntarily or discharged. Any use of restraints should be compliant with regulatory guidelines and be documented with a timed physician order, reevaluations, and a nursing flow sheet. If a patient requires involuntary hospitalization, providers should document why the patient is a danger to self or others. If the patient is discharged, the record should reflect the decision-making as to why the patient is estimated to be at low risk of imminent self-harm, including description of the home situation (eg, lack of potentially lethal methods of suicide), information from collateral sources, and the follow-up plan.

**DISPOSITION**

Psychiatric Hospitalization

Following principles of empathetic, patient-centered, collaborative care, voluntary hospitalization is preferable to involuntary hospitalization. The efficacy of hospitalization as a long-term preventive measure is controversial, and a rapid referral to outpatient care is often preferable when feasible and appropriate. Hospitalization is not proven to prevent future suicide and may even precipitate adverse psychiatric consequences (eg, increased feelings of hopelessness and dependency). Still, despite the lack of hard data, hospitalization remains a primary intervention when patients are deemed acutely suicidal. Effective inpatient (and outpatient) therapeutic approaches include dialectical behavioral therapy, cognitive behavioral therapy, and Collaborative Assessment and Management of Suicidality (CAMs). Civil commitment statutes differ among the 50 states and the District of Columbia. Most states have “emergency commitment” provisions that typically require the patient (1) has mental illness and (2) poses a threat to self or others. The length of emergency commitments vary by state, from 72 hours to 15 days. In some states, patients who agree to hospitalization may still need involuntary commitment papers completed for transport to a receiving psychiatric facility; this is to provide the legal basis for holding them if they change their mind during the trip.

Discharge

Many patients who report suicidal thoughts or have symptoms of depression can be safely managed as outpatients if the risk of subsequent suicide is judged to be acceptably low. Although the clinician can make this determination in many cases (see Figs. 105.1 and 105.2), evaluation by a mental health professional can be useful if the safety of outpatient management is in doubt, and nurses also play an important role in discharge planning. A family member or friend should agree to stay with—or be immediately available to—the discharged patient until follow-up is provided. The patient should be discharged to a stable and supportive home environment without access to guns or lethal medications. The discharge planning process should ideally include at least one of the following: brief patient education, joint safety planning, lethal means restriction counseling, referral for outpatient care, and “caring contacts.”

**Brief patient education** for suicide prevention should include the use of verbal and written information and “teach back” techniques whereby the patient explains the information back to the provider. Information can include a personalized list of risk and protective factors, home care, follow-up, and warning signs that should trigger a call for help. The education process should engage the patient in an empathetic and respectful manner and should, with patient consent, include family members or close friends. Educational materials are available from a number of national organizations.

In joint safety planning, a provider works with a patient to develop a plan regarding what to do should symptoms worsen (Table 105.5). The plan should be in the patient’s own words and easy to understand, and it should include warning signs, a list of coping strategies, and resources such as hotlines or contact information for trusted family or friends. The National Suicide Prevention Hotline (1-800-273-TALK [8255]) should be given to all discharged patients; this national toll-free telephone and online...
Suicidal behavior: prior suicide attempts or self-injurious behavior
Current/past psychiatric disorders: especially mood disorders, psychotic disorders, alcohol/substance abuse, ADHD, TBI, PTSD, Cluster B personality disorders, conduct disorders (antisocial behavior, aggression, impulsivity)
Key symptoms: anhedonia, impulsivity, hopelessness, anxiety/panic, insomnia, command hallucinations
Family history: of suicide, attempts or Axis I psychiatric disorders requiring hospitalization
Precipitants/Stressors/Interpersonal: triggering events leading to humiliation, shame or despair (eg, loss of relationship, financial or health status—real or anticipated); ongoing medical illness (esp. CNS disorders, pain); intoxication; family turmoil/chaos; history of physical or sexual abuse; social isolation
Change in treatment: discharge from psychiatric hospital, provider or treatment change
Access to firearms

Suicide and lethal means counseling for suicidal patients is supported by multiple physician organizations and listed as a “best practice” for suicide prevention.78,84 Clinicians should counsel suicidal patients and their families to remove guns temporarily from the home for storage off-site in an appropriate location (e.g., a gun shop, police department, or with a family member if legal under state law); gun locks or cabinets to which the patient has no access are an alternative.

Discharged patients should also be referred for outpatient care, ideally within 72 hours because suicide risk remains high shortly after discharge from the ED.85 Evidence-based outpatient treatment can reduce future suicide risk, and emergency clinicians play a key role in linking patients to care.73 A significant number of discharged ED patients do not keep their follow-up appointments, but compliance with follow-up may be increased by making a specific appointment for patients. Having the family or friends help ensure that the patient keeps the follow-up appointment is another strategy. In addition, it may be helpful to provide physician contact information or to provide a list of community mental health resources. With the patient’s consent, the physician can send visit information to the patient’s primary care provider or outpatient referral provider to enhance continuity of care.

Another possible intervention for discharged patients is caring contacts, or brief communications after discharge.59,86,87 These empirically-supported interventions take a variety of forms, including text messages, emails, phone calls, and postcards, and they may be one- or two-directional. An automated system, supported by the electronic health record, can facilitate the process, or the contacts can be made by a clinical or non-clinical ED staff member.

### KEY CONCEPTS

- Suicide is a common—but preventable—cause of death.
- Suicidal thoughts or behaviors are often triggered by a treatable or reversible short-term crisis, and most attempt survivors are grateful to be alive.
- Suicide risk changes over time, and estimation of imminent risk is not evidence based at this time.
- Routine “screening” laboratories provide little value for most ED patients with self-harm behaviors. Evaluation should be directed at specific concerning signs or symptoms.
- Many suicidal individuals see a physician shortly before their death. An ED visit for suicidal thoughts or behaviors represents a crisis and a teachable moment.
- An empathetic, patient-centered, collaborative approach that incorporates information from collateral sources (e.g., family) can optimize care.
- Suicide precautions in the ED include appropriate use of “sitters” and, when necessary, physical and chemical restraints and involuntary commitment.
- Brief risk assessment by the emergency clinician can identify patients in need of a comprehensive evaluation and consultation with a mental health specialist (if available).
- Patients at low risk of suicide may be discharged home to a safe and supportive environment without access to guns or toxic medications.
- Discharged patients should receive education and safety planning in the ED and should have early mental health follow-up appointment.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
105.1. Which of the following statements about suicide is true?  
A. Many suicide attempts occur during an acute crisis.
B. Suicide rates are highest in older men.
C. Suicidal behavior may be chronic.
D. Suicidal patients are usually ambivalent about dying.
E. All of the above are true.

Answer: E. Many suicide attempts occur in response to a crisis that may be time limited or resolvable. Suicide rates are particularly high in older white men. With the exception of psychotic patients, suicidal patients are usually ambivalent about dying. An example of chronic suicidal behavior is drinking in the face of liver disease.

105.2. Which of the following statements about suicide is true?  
A. Blacks attempt suicide more than whites.
B. Men attempt suicide more than women.
C. Marriage decreases the likelihood of suicide.
D. Pregnancy increases the risk of suicide.
E. Suicide rates are highest among female teens.

Answer: C. Marriage and pregnancy/motherhood decrease suicide risk. Whites attempt suicide more than blacks, with the highest rate among older white men. Women attempting suicide far more often than men but do not choose lethal means and therefore have a lower success rate.

105.3. Which of the following is a risk factor for suicide?  
A. Prior suicide attempt
B. Access to firearms
C. Alcohol abuse
D. Veteran status
E. All of the above

Answer: E. Additional suicide risk factors include, but are not limited to: adolescence and older age; male gender; certain races/ethnicities (White, American Indian, Alaskan Native); mental disorders; substance abuse; prior suicide attempt; psychosocial stressors (eg, recent psychiatric hospital discharge, history of trauma or abuse, terminal illness, chronic pain, hopelessness, impulsiveness); environmental stressors (eg, job loss, bereavement); and sociocultural factors (eg, isolation, poor access to mental health care, stigma against seeking help, or media exposure to suicide).

105.4. Most completed suicides involve which of the following?  
A. Falls
B. Firearms
C. Piercing
D. Poisonings
E. Suffocation

Answer: B. Fifty percent of completed suicides involve firearms. Seventy percent of attempted suicides involve poisoning.

105.5. Discharge planning for suicidal patients should include which of these elements?  
A. Counseling about reducing access to guns and toxic medications
B. Involvement of family or friends
C. Rapid referral to outpatient mental health
D. Written materials with warning signs and hotline numbers
E. All of the above

Answer: E. All of the listed elements are recommended components of ED care and discharge planning for patients evaluated for suicidal thoughts or behaviors but deemed safe for discharge home.

105.6. A 33-year-old Caucasian man presents with agitation and suicidal ideation. He has a long history of schizophrenia and is currently taking olanzapine and occasional clonazepam. He was hospitalized 3 weeks prior for an accelerated psychotic episode and released on an increased dose of olanzapine. His family brought him home today after visiting him in his apartment and finding him in a room with all the lights off. They note he has been unable to work for more than 2 years. He was formerly employed as an engineer. Your examination is remarkable for a blunted affect, moderate pressured speech, and a depressed mood. What is the most appropriate intervention?  
A. Addition of sertraline to olanzapine, 2-day follow-up
B. Admission to psychiatry unit
C. Increase olanzapine, release with family

Answer: C. Increase olanzapine, release with family.
D. Overnight emergency department (ED) observation, 2-day psychiatry follow-up
E. Parenteral ziprasidone, release with family

Answer: B. Approximately 10% of schizophrenic patients will kill themselves. Psychotic patients who kill themselves are often unmarried whites of high intelligence. A recent psychiatric hospitalization is a suicide risk factor, particularly during the first month post discharge. This patient is high risk and needs admission.

105.7. Which of the following statements concerning risk assessment of suicidal patients is true?
A. An empathetic approach will reinforce malingering behavior and subsequent ED visits.
B. For patients at low risk of imminent suicide, providers can consider discharge without formal consultation with a mental health professional.
C. Intoxicated patients who, once sober, disavow prior suicidal statements do not need a suicide risk assessment.
D. Routine screening labs should include serum chemistries and urine toxicologic panels.
E. Suicidal patients can be permitted to leave the ED prior to a risk assessment as long as they sign “Against Medical Advice” paperwork.

Answer: C. In a step-wise manner, the ED provider can complete a brief risk assessment to identify which patients do (or do not) require a comprehensive evaluation with a mental health professional. Diagnostic testing should be targeted to individual patients as clinical indicated. An empathetic approach can enhance patient evaluation and care and should be used with all suicidal patients. Acute and chronic alcohol use are both suicide risk factors; even if a patient denies suicidality once sober, a risk assessment may be prudent. No suicidal patient should be allowed to leave the ED before the risk assessment is complete.

105.8. Which of the following statements about involuntary commitment is true?
A. It is not associated with adverse psychiatric consequences.
B. It lowers the rate of future suicides.
C. Most states mandate attempts at involuntary commitment if there is imminent self-harm.
D. Patients who volunteer for admission may still need commitment papers.
E. Statutes are consistent among the states.

Answer: D. Statutes vary widely among the states. Some states require commitment papers even in cases of voluntary admission. Only two states mandate commitment in the face of suspected imminent self-harm. Involuntary commitment does not lower the rate of future suicides and is associated with adverse psychiatric consequences.
Arthritis and its related disease states represent the most common cause of disability in the United States. Because of the pain and limitations associated with joint inflammation, patients with complaints stemming from arthritis present frequently for emergent evaluation. Many of the arthritides are associated with premature mortality, and their treatments are associated with adverse effects. The inflamed joint may be a diagnostic clue to a serious systemic illness, and unmasking of true arthritis emergencies can prevent or attenuate devastating disability.

Arthritis and related conditions are among the oldest disease states described. Roman, Greek, and Egyptian cultures made reference to gout and rheumatoid arthritis and even associated these maladies with diet and socioeconomic status. Many celebrated figures in medicine, such as Hippocrates, Galen, and Sydenham, contributed to the description, classification, and treatment of rheumatic disorders. Reiter’s syndrome, however, takes its name from a discredited Nazi war criminal. Many, including the physician who first bestowed the eponym in the English literature in 1942, Ephraim Engleman, advocate for the generic term reactive arthritis.

Pathophysiology
As opposed to synarthrotic suture joints of the skull and amphiarthrotic fibrocartilage unions like the pubic symphysis, the joints of concern in acute arthritis are the synovial or diarthrotic (moving) joints. These synovial joints are composed of two ends of subchondral bone covered by articular cartilage, surrounded by a capsule that is lined with a thin synovial membrane and supported by ligaments, tendons, and muscle (Fig. 106.1A).

Articular cartilage is an avascular, aneural tissue composed of a matrix of collagen fibers and proteoglycans synthesized by chondrocytes. The properties of articular cartilage allow tremendous load bearing. Together with the viscous lubricating synovial fluid, an ultrafiltrate of blood supplemented with hyaluronic acid and low-molecular-weight proteins, the cartilage that articulates joint movement is nearly frictionless.

Whereas disease-specific changes receive further detail in subsequent sections, the final common pathway of arthritis is triggered by trauma, infection, or the endogenous cell and humoral inflammation stimulated by infection or autoimmune disease.

The pathologic process of arthritis can unfold during hours or years. Tissue destruction can be mediated by fast-acting catabolic pathways, or long-term changes to the composition of cartilage’s extracellular matrix may be brought on by abnormal loading patterns or trauma. The synovium plays a critical role in crystal deposition and inflammatory response (see Fig. 106.1B).

Clinical Features
History
Patients with joint problems who come to the emergency department (ED) typically complain of pain, although the distribution and chronicity can vary markedly. In addition to eliciting a history and associated symptoms, the clinician should determine whether the source of the inflammation or pain is articular or periarticular (outside the joint capsule).

True arthritis produces generalized joint pain, warmth, swelling, and tenderness. Discomfort increases with both passive and active motion of the joint because the inflamed synovium is exquisitely sensitive to stretching, and because all parts of the joint are involved in the inflammatory process. By contrast, periarticular inflammation (bursitis, tendinitis, or localized cellulitis) tends to be more focal.

If the site of the patient’s pain is articular, classifying whether the arthritis is monarticular (eg, septic arthritis or gout) or polyarticular may aid in diagnosis. Polyarticular arthritis may be symmetrical (eg, rheumatoid or drug-induced) or asymmetrical (eg, rubella, acute rheumatic fever [ARF], Lyme disease, or gonococcal arthritis). In addition, it may also be migratory (eg, gonococcal or rubella), subsiding in one area before presenting in another, or additive, remaining in the first joint and progressing to additional joints (Table 106.1).

The distribution of joint involvement may give clues to the disease: the first metatarsophalangeal (MTP) joint is classically affected in gout; the metacarpophalangeal (MCP) joints and proximal interphalangeal (PIP) joints in rheumatoid arthritis; and the distal interphalangeal (DIP) joints and the first carpometacarpal joint in osteoarthritis. Patients with inflammatory arthritis may have low-grade fever; high fever with chills is more suggestive of a septic arthritis. Morning stiffness (synovial gel phenomenon) and improvement of symptoms with activity suggest inflammatory arthritis, whereas improvement with rest suggests mechanical disorders. Concomitant renal stones suggest gout, genital ulcerations occur in Behçet’s disease and reactive arthritis, and a purulent urethral discharge suggests gonococcal arthritis or reactive arthritis. The use of isoniazid, procainamide, and hydralazine can precipitate lupus, and thiazides can increase the serum uric acid level, leading to gouty arthritis.
Physical Examination

General Examination

The physical examination searches for evidence of both local and systemic manifestations of rheumatic diseases (Table 106.2).

Joints

Joints are examined for warmth, effusion, synovial thickening, deformity, range of motion, pain on actively loaded motion, and tenderness (generalized or localized, articular or periarticular). Localized tenderness and pain associated with active movement are more likely to be periarticular in origin. Generalized tenderness and pain, both at rest and with active and passive motion, suggest joint involvement.

Spine

The spine evaluation is best performed with the patient standing; the vertebral column is assessed for abnormal curvature or asymmetry. Although supporting evidence is scant, Schober’s maneuver...
is used to assess for the limitation of the lumbar spine motion that occurs in ankylosing spondylitis (in a healthy standing patient, the 15 cm line that begins 5 cm below L5 and runs to 10 cm above L5 should lengthen to 20 cm or more when the patient bends to touch the ground).  

**Upper Extremities**

A shoulder affected by chronic arthritis or bursitis will have atrophy of the deltoïd muscle. Early signs of joint inflammation in the elbow are limitation of extension and an increase in the normal angle at which the patient holds the elbow at the side. Assessment of the wrist is difficult because it may not be obviously swollen. Discomfort and decreased range of motion, particularly on extension, may indicate synovial involvement.

The hand and wrist provide many clues to the presence of long-standing rheumatic diseases: MCP and PIP joints are affected in rheumatoid arthritis; and the first carpometacarpal, PIP, and DIP joints are affected in osteoarthritis. The fingers may be swollen or sausage-like in appearance, an indication of psoriasis or reactive arthritis. Subluxation at the MCP joints, ulnar deviation, and swan-neck deformities occur in rheumatoid arthritis. The nails may have pitting characteristic of psoriatic arthritis.

**Lower Extremities**

Inflammation affecting the hip joint can be manifested as pain in the anterior thigh, knee, or groin. A hip joint effusion will cause the patient to hold the hip partially flexed. An externally rotated and abducted leg in pediatric patients strongly suggests infection, as opposed to transient synovitis or Legg-Calvé-Perthes disease.

An effusion of the knee joint is relatively easy to detect when it appears as a ballotable fullness medially and laterally. Fullness of the popliteal fossa may indicate Baker’s cyst. Passive range of motion may elicit crepitus (suggestive of degenerative joint disease) or clicking (suggesting a meniscal tear). Tibiotalar joint effusions produce swelling under the medial malleolus and make it difficult to palpate the extensor hallucis longus tendon. Tenderness, warmth, and swelling of the great toe MTP joint occur in cases of gout but can also occur with osteoarthritis and rheumatoid arthritis. Sausage-like swellings of the toes are seen in reactive arthritis.

**DIAGNOSTIC TESTING**

**Laboratory Tests**

Laboratory testing conveys only modest diagnostic value in the ED evaluation of arthritis. Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) level, white blood cell (WBC) count, and serum uric acid level are best used in the context of evaluating the likelihood of specific forms of arthritis; no guidelines or studies exist supporting the use of blood testing as a general screen for acute undifferentiated arthritis in the ED.

**Radiologic Tests**

**Plain Radiography**

Plain radiographs are more helpful in patients with chronic disease than in those with acute arthritis. Common findings that help distinguish the different forms of arthritis are shown in Table 106.3. For lower extremities, weight-bearing radiographs can better evaluate joint space narrowing.

**Computed Tomography, Magnetic Resonance Imaging, and Sonography**

Other radiologic modalities are occasionally performed as part of the evaluation of arthritis in an emergency setting. Ultrasonography compares favorably with plain radiography in the evaluation of joint effusions and synovitis associated with rheumatoid arthritis, and it is useful to evaluate pediatric hip effusion and to guide arthrocentesis. Magnetic resonance imaging (MRI) is well suited for imaging of cruciate ligaments of the knee, detection of early edema in periarticular structures and fluid collection in tendon sheaths, and determination of the extent of cartilage destruction. MRI is also the study of choice for diagnosis of osteonecrosis and is more sensitive than plain radiography for early osteomyelitis.

**Arthrocentesis**

Arthrocentesis is a crucial diagnostic modality for the diagnosis of septic arthritis or crystal-induced joint disease.

**Indications and Contraindications.** The emergency indications for arthrocentesis in the evaluation of joint pain are to obtain joint fluid for analysis, to drain tense hemarthroses in patients with trauma or hemophilia (of the elbows, knees, or ankles and after the appropriate clotting factor replacement), to evaluate whether a laceration communicates with the joint space,
and to instill analgesics and anti-inflammatory agents for the treatment of acute and chronic arthritis.

The American College of Rheumatology guidelines recommend arthrocentesis to evaluate patients with an established history of arthritis who present with fever and new joint pain or effusion. Although scant literature on inoculated joint spaces exists, emergency arthrocentesis through overlying cellulitis is relatively contraindicated, and one should avoid the infected area if possible during puncture. Coagulopathy is the other relative contraindication, but arthrocentesis was safely performed in 99.8% of patients with therapeutic international normalized ratios (INRs) in one retrospective review. Arthrocentesis of prosthetic joints should be performed only to rule out infection and is best done in consultation with an orthopedic surgeon.

Complications. The primary complications of arthrocentesis are bleeding or infection in the joint space, reaction to anesthetic agents, and long-term corticosteroid-related complications. Dry taps (when no fluid is aspirated after joint puncture) are more common in patients with chronic arthritis because of obstructing tophi or anatomic abnormalities in the synovium and periarticular tissues. Use of a smaller syringe or a larger needle may help in such cases.

Technique. Successful joint aspirations begin with positioning of patients so that they are comfortable, with adequate exposure and cushioned support for the joint. Muscle tension during the procedure can reduce the joint volume, making the procedure more difficult. Carefully palpate the bone landmarks and prepare the skin with an aseptic technique. Adequate local anesthesia is achieved either by use of topical vapo-coolant or local infiltration with anesthetic solution, such as 1% or 2% lidocaine. With an 18- or 19-gauge (large joints) or 20- to 22-gauge needle (smaller joints) attached to a syringe, the joint space is punctured and aspirated with care taken to avoid abrasion of the articular cartilage. Excessive suction may bring synovial tissue into the needle, limiting aspiration. After aspiration, a long-acting anesthetic can be instilled to alleviate pain. As a general rule, do not instill steroids unless a septic arthritis has been excluded. For approaches to specific joints, see Box 106.1.

Synovial Fluid Examination. Analysis of synovial fluid is essential for identification of crystalline and suppurative causes of acute arthritis (Table 106.4).

General Appearance. Bedside inspection of synovial fluid for color, clarity, and viscosity can provide diagnostic clues. Normal synovial fluid is clear and colorless, with a viscosity that permits stretching of a “string” of fluid between the thumb and forefinger. Inflamed fluid is more opaque from an elevated WBC count, with a viscosity more like water because of enzymatic breakdown of glycosaminoglycans. Hemarthrosis is manifested after acute trauma or in the presence of coagulopathy, particularly with hemophilia. Lipohemarthrosis indicates ligamentous injury or an intra-articular fracture, and brownish synovial fluid may suggest the rare diagnosis of pigmented villonodular synovitis.

Synovial Fluid Studies. Routine laboratory analysis includes a cell count with differential, Gram stain, and crystal analysis; synovial glucose and protein concentrations are of little diagnostic

**WRIST: RADIOCARPAL JOINT (DORSAL APPROACH)**
1. Identify landmarks by palpating the Lister tubercle at the distal end of the dorsal radius.
2. Palpate the extensor pollicis longus tendon, which passes over the radial side of the Lister tubercle (best palpated while the wrist is in extension). You will insert the needle on the ulnar side of the extensor pollicis longus tendon, just distal to the Lister tubercle.
3. Lay the wrist on a cushion so that it is flexed 20 to 30 degrees.
4. Insert a 22-gauge needle dorsally.

**ELBOW: RADIOHUMERAL JOINT (LATERAL APPROACH)**
1. Identify landmarks by extending the elbow and then palpating the depression between the lateral epicondyle of the humerus and the head of the radius.
2. Keep your finger on the radial head, flex the patient’s elbow, pronate the forearm, and lay the palm on a flat surface.
3. Insert a 20-gauge needle just distal to the lateral epicondyle, directed medially.

**SHOULDER: GLENOHUMERAL JOINT (POSTERIOR APPROACH)**
1. Lay the patient’s arm, internally rotated, across the waist.
2. Identify the posterolateral corneal of the acromion.
3. Insert a 20-gauge needle 2 to 3 cm inferior to this point, directed anteriorly and medially (and slightly superiorly) toward the coracoid process.

**HIP: ACETABULOFEMORAL JOINT (LATERAL APPROACH)**
1. Lay the patient supine and internally rotate the affected leg.
2. Palpate the greater trochanter.
3. Insert a 3.5-inch 18-gauge needle superiorly to the trochanter, horizontal and parallel to the stretcher. If the femoral neck is encountered, withdraw 2 mm to 4 mm and redirect slightly cephalad until synovium is aspirated.

**KNEE: PATELLOFEMORAL JOINT (MEDIAL APPROACH)**
1. Flex the knee 15 to 20 degrees (often achieved with a rolled towel under the knee). The foot should be perpendicular to the floor.
2. Palpate the anteromedial patellar edge at the patellar midpoint or superior portion.
3. Insert an 18-gauge needle 1 cm medial to this point, directed toward the posterior surface of the patella.

**ANKLE: TIBIOTALAR JOINT (ANTEROMEDIAL APPROACH)**
1. With the patient supine, have the patient plantarflex the foot.
2. Identify the anterior tibial tendon.
3. Insert a 3.5-inch 20- or 22-gauge needle medial to this tendon in the depression at the anterior edge of the malleolus.

**METATARSOPHALANGEAL JOINT (DORSOMEDIAL APPROACH)**
1. Locate the great toe. Identify the distal metatarsal head and the proximal base of the first phalanx.
2. Identify the extensor tendon by asking the patient to extend the great toe.
3. While the patient is supine, flex the toe 15 to 20 degrees, and then apply traction.
4. Insert a 22-gauge needle dorsally just medial to the extensor tendon.

**LR**, Likelihood ratio; **SA**, septic arthritis.

**Nongonococcal Bacterial Septic Arthritis**

**Principles**

**Epidemiology.** In prospective series of patients presenting to the ED with monoarticular arthritis prompting arthrocentesis, significant percentages of patients had bacterial joint infections. The incidence of septic arthritis in the general population is approximately two to 10 cases per 100,000 per year, with bimodal age distribution peaks for young children and adults older than 55 years old. Additional risk factors that raise the likelihood of septic arthritis include age over 80, low socioeconomic status, injection drug abuse (in which joint infections typically involve the axial skeleton but can involve extremities), alcoholism, diabetes, skin infections, advanced human immunodeficiency virus (HIV) infection or other immunocompromised states, chronic arthritis (particularly rheumatoid, crystalline, and degenerative osteoarthritis), and recent intra-articular corticosteroid injections or prosthetic implants.

**Pathophysiology.** Bacterial pathogens infect diarthrotic joint spaces most commonly by hematogenous spread, but direct inoculation and contiguous spread from bone or soft tissue infections also occur. Once in the joint space, bacteria proliferate essentially unchecked in the highly vascular synovium, which has no limiting basement membrane. Bacterial components and toxins, as well as the inflammatory cascade they induce, trigger synovial proliferation with neovascularization and subsequent enzymatic, cellular, and cytokine degradation of articular cartilage. Septic arthritis, unless it is rapidly recognized and treated, results in serious disabling morbidity in up to half of patients, with significant mortality rates as well.

Septic arthritis can occur simultaneously with other forms of arthritis, particularly rheumatoid arthritis and gout. The diagnosis of infectious arthritis in a patient with known crystal arthritis can be challenging because acute flare-ups of gout or pseudogout can cause fever, and crystals can precipitate in an infected joint. For this reason, arthrocentesis for Gram stain and culture should be considered in select cases.

**Microbiology.** The microbiology of nongonococcal arthritis has remained fairly constant over time, except for the decline of *Haemophilus* and pneumococcal species in the postimmunization era, and the rise of methicillin-resistant *Staphylococcus aureus* (MRSA). Acute nongonococcal septic arthritis in adults is caused most often by gram-positive organisms (75% to 90%), followed by...
Prosthetic joint infections are classified as early (within a month of surgery) or late. Late infections can be caused by hematogenous spread from another infection or by indolent organisms introduced at surgery that may not surface for up to a year. Because the joint is literally replaced, antibiotic bioavailability and host immune response are both impaired in the prosthetic environment. A wide range of culprit organisms have been identified; MRSA incidence is rising. Arthrocentesis diagnosis of a suspected prosthetic joint infection is best done in consultation with the operating surgeon. A synovial WBC count of more than 1100/µL or a pleocytosis of greater than 64% PMN cells is sensitive and specific for infection in the setting of prosthetic joints.

Clinical Features. Patients with septic arthritis present with fever, joint pain, and effusion, typically in a single large joint (the knee is most common). Moderate fever occurs in 50% of cases but may be less common in the presence of advancing age or immunosuppressive states. Rigors and chills are reported in only 20% of patients. Polyarticular presentation occurs in 20% of cases, particularly in patients with rheumatoid arthritis or chronic joint disease, meningococcal infections, or overwhelming sepsis. Other physical signs, such as edema, tenderness, and decreased range of motion, have not been adequately evaluated for their prognostic value.

Diagnostic Testing. Although laboratory evaluation typically includes complete blood cell count, ESR, and CRP level, a WBC count above 10,000/µL and an ESR above 30 mm/hr only

by gram-negative bacilli (10% to 20%) and then anaerobes, mycobacteria, fungal, and other unusual organisms. Neisseria gonorrhoeae accounts for only 20% of cases of monoarticular septic arthritis and more commonly is manifested with polyarthritis; it is discussed separately. Select populations have higher propensities for specific infecting organisms (Table 106.5).
minimally increase the likelihood of septic arthritis. In a prospective trial of pediatric knee arthritis in Lyme-endemic areas, no child with an ESR below 40 mm/hr with an absolute neutrophil count less than 10,000 per mm$^3$ had septic arthritis. However, systematic reviews show insufficient evidence for a normal CRP level, ESR, WBC count, or procalcitonin level to take septic arthritis below the threshold for further evaluation in adults. Serum blood cultures reveal the causative organism less than half of the time.

Radiographs demonstrate only soft tissue swelling if it is present; the bone changes of septic arthritis are not usually present on the initial examination. Radiographs may help assess for osteomyelitis or serve as a baseline for future comparisons. Computed tomography (CT) or MRI may be helpful in evaluating early bony changes or soft tissue edema in areas difficult to palpate or aspirate, such as the sacroiliac joint.

Synovial fluid analysis is the best test for septic arthritis. The likelihood of septic arthritis rises with synovial WBC count. Polymorphonuclear cell concentrations above 90% are also associated with an increased likelihood for septic arthritis. In a meta-analysis of four trials, synovial lactate levels greater than 5.6 mmol/L had LR+ from 2.4 and above, although these values were not obtained from modern point-of-care devices. Synovial lactate dehydrogenase (LDH) levels above 250 U/L are sensitive for septic arthritis, and LDH levels below this threshold seem to exclude septic arthritis, according to one study. Low synovial glucose and high protein concentrations are neither sensitive nor specific for septic arthritis. Gram stain will show bacteria in a majority of infected joints. Synovial fluid cultures for both aerobic and anaerobic organisms should be performed.

Management. Early diagnosis of septic arthritis is crucial; substantial delays directly worsen prognosis. Empirical antibiotic therapy is based on Gram stain or the presumptive consideration of likely organisms. Once the diagnosis is made, hospitalization is indicated for administration of intravenous (IV) antibiotics and needle, arthroscopic, or open drainage of the affected joint. Whereas the utility of performing or omitting joint drainage has not been prospectively studied, retrospective reviews suggest good cure rates with drainage, with outcomes dependent on initial severity. More severe cases require frequent, potentially daily joint aspirations.

There are no randomized controlled trials of antibiotic regimens in septic arthritis. Antibiotic selection is initially based on Gram stain results and then adjusted on the basis of final culture results and sensitivities. For gram-positive organisms, the initial
drug of choice is vancomycin 30 mg/kg daily in two divided doses, as MRSA is frequently caustive. For gram-negative bacilli, use a third-generation cephalosporin, such as ceftriaxone 2 g IV once daily, cefotaxime 2 g IV three times a day, or ceftazidime with gentamicin (especially if *Pseudomonas* infection is suspected). Although no trials of antibiotic duration have been reported, antibiotic therapy is generally continued parenterally for 2 to 4 weeks, depending on the response, and followed by 2 to 6 weeks of oral antibiotic therapy.

Open arthrotomy for drainage is indicated for failure to respond to therapy within a few days of hospitalization, the presence of osteomyelitis, involvement of the hips or shoulders, or the presence of any prostheses. Parenteral opioid analgesics and immobilization are recommended for pain and discomfort.

Gonococcal Arthritis

**Principles.** Gonococcal arthritis was considered the most common infective arthritis in the United States in the 1970s and 1980s and remains the most common form of joint infection in the sexually active population. In recent years, the incidence has decreased, most likely because of a general decline of N. gonorrhoeae prevalence, particularly of the more virulent strains. Host risk factors for dissemination of gonococcal infection include pregnancy, menstruation, and complement deficiency. There has been a 4:1 female predominance, attributed to mucosal infections in women more likely to be asymptomatic.

Gonococcal arthritis represents a clinical and pathologic course distinctly different from that of other bacterial infections and is less likely to create long-term joint disease.

**Clinical Features.** Systemic gonococcal infection complicates 0.5% to 3% of mucosal infections and is manifested with two somewhat overlapping musculoskeletal syndromes. The first is a localized septic arthritis, more commonly oligoarthritis than monoarthritis, predominantly in the wrist, knee, or ankle. The effusions may be modest. True disseminated gonococcal infection (sometimes termed arthritis-dermatitis syndrome) is manifested with bacteremia, diffuse migratory arthralgias, characteristic skin lesions, and tenosynovitis (Fig. 106.3). A similar syndrome has been recognized as a result of *Neisseria meningitidis* infection.

**Management.** Microbiologic diagnosis is difficult, because both synovial and blood cultures are positive for gonococcus in no more than half of cases. The diagnostic yield is higher when specimens are plated on Thayer-Martin medium and even greater with the use of polymerase chain reaction (PCR). Synovial fluid often yields a positive Gram stain result, and the synovial WBC count tends to be lower than in nongonococcal arthritis (generally 40,000 to 60,000 cells/mm³). Cervical, urethral, rectal, and pharyngeal cultures are positive in up to 75% of cases, so all mucosal orifices of the patient (and partner, if possible) should be cultured appropriately. In disseminated gonococcal infection, the skin lesions often contain the gram-negative diplococcus.

The most recent Centers for Disease Control and Prevention (CDC) guidelines recommend hospitalization, especially if etiology or compliance is uncertain, and treatment with intramuscular (IM) or IV ceftriaxone 1 g every 24 hours plus a single dose of oral azithromycin 1 g. Alternatively, IV cefotaxime or cefotaxime 1 g three times daily plus azithromycin 1 g orally in a single dose, with “step down” transition within 24 to 48 hours to oral antimicrobials, dictated by sensitivities, for at least a week.13 Partners should be evaluated. Presumptive treatment of *Chlamydia* is also advised.

Repeated therapeutic arthrocentesis may not be necessary in this form of septic arthritis. With prompt antibiotic therapy, residual joint problems are uncommon.

Gouty Arthritis

**Principles**

**Epidemiology.** Acute intermittent gout typically is manifested in middle-aged men or postmenopausal women, often in the setting of excess alcohol consumption or dietary indiscretion, acute physiologic stressors (such as, illness, trauma, or surgery), or new medications. Its prevalence in the United States is estimated at 4% of the population and up to 13% of the population older than 80 years old.14 Risk factors include chronic obesity, hypertension, diabetes, thiazide diuretics or cyclosporine use, and lead or radiocontrast exposure. Purine-rich diets (meat; seafood, especially anchovies and shellfish; beer; and legumes) predispose at-risk individuals to attacks; high-fructose corn syrup and soft drinks are also implicated.15 High dairy and coffee consumption have been shown to decrease risk.

**Pathophysiology.** Gout results from inflammation caused by the acute precipitation of uric acid crystals from supersaturated extracellular fluid. Uric acid is a normal metabolic end product of purine metabolism. Hyperuricemia results from its underexcretion in the kidney or, less commonly, from systemic overproduction caused by inborn errors of metabolism and mycoproliferative diseases. During an attack of gouty arthritis, the crystals are ingested by PMN cells, resulting in cytokine release and an inflammatory synovial reaction.

Asymptomatic hyperuricemia typically exists for decades, and less than a quarter of these patients have acute manifestations. Furthermore, not all patients with elevated uric acid levels or even joint crystals have acute attacks, and many patients with an acute gouty arthritis have a normal uric acid level.

**Clinical Features.** Gouty attacks most commonly occur in the great toe MTP joint (*podagra*, up to 75%, with 90% of patients eventually experiencing this joint flare), the knee (*gonagra*), the ankle, and the tarsal joints. Usually only one joint is involved initially, but approximately 20% of patients can experience polyarticular involvement, bursitis, tenosynovitis, or even skin inflammation. The pain is often exquisite at onset. Systemic symptoms can include fever. Without treatment, the attack is self-limited, peaking during 24 to 48 hours and lasting about a week.

Subsequent attacks tend to be closer together, involve more joints, and last longer, eventually morphing into the final stage of chronic gouty arthritis after a decade, if untreated. Long-term sequelae include renal stones and tophi in the musculotendinous

---

*Fig. 106.3. Pustular lesion with disseminated gonococcal infection. (From Mandell GL, Bennett JE, Dolin R, editors: Mandell, Douglas, and Bennett’s principles and practice of infectious diseases, ed 6, Philadelphia, 2005, Elsevier/Churchill Livingstone.)*
units, such as the olecranon bursa, Achilles tendon, ulnar surface of the forearm, hands and fingers, knees, feet and toes, and even the helix of the ear.

**Diagnostic Testing.** The observation, with a polarizing microscope, of intracellular negatively birefringent crystals in joint fluid aspirate remains the “gold standard” for diagnosis of gouty arthritis.

**Laboratory Tests.** Whereas higher levels of serum uric acid are commonly seen in gouty patients, this laboratory finding is not helpful in establishing the diagnosis of gout in the acute setting. Urate levels can be transiently normal, a process thought to be mediated by the uricosuric effects of endogenous adrenocorticotropic hormone (ACTH) and epinephrine, released as part of the pain response. Given the association of gout and renal insufficiency and the nephrotoxicity of several therapies, checking renal function is prudent.

**Radiologic Tests.** During an acute attack, radiographs of the affected joint will show only soft tissue swelling, but long-standing disease produces typical asymmetrical bone erosions slightly removed from the joint (as opposed to rheumatoid arthritis erosions, which are more proximal to the articular surface—see Fig 106.7). The crystal deposits of gout also cause an overhanging margin of soft tissue by the erosion. Dual-source, dual-energy CT using a mineral composition algorithm has shown promise in a small trials and observational series for diagnosis of uric acid collections in joints.18,19 Ultrasound has also been studied to evaluate gout, because crystalline material in gouty joints reflects sound waves more strongly than soft tissue and cartilage. An protocol for experienced ultrasonographers to evaluate hyperechoic aggregates and the “double contour” sign of crystal deposition showed adequate sensitivity and specificity in a prospective case-control study of patients recruited from rheumatology clinics.20 However, it’s not yet clear if this approach can help diagnose patients presenting to the ED with acute gout flares.

**Management.** Gout therapies are divided into acute treatment and long-term prophylaxis. Prophylaxis is generally not an emergency consideration, but many patients present with breakthrough attacks. New guidelines for gout recommended that prophylactic agents (such as, allopurinol), or newer agents (such as, febuxostat and probenecid) should neither be stopped nor initiated during an acute attack.21 ED pharmacologic mainstays for acute gout are nonsteroidal antiinflammatory drugs (NSAIDs; including cyclooxygenase 2–selective agents), corticosteroids (including ACTH), and colchicine. Caution is exercised with use of these agents because hypertension, diabetes, and renal and vascular disease are prevalent in this cohort of patients.

**Nonsteroidal Antiinflammatory Drugs.** Whereas NSAIDs, particularly indomethacin, are considered first-line therapy for acute gout attacks, there is little evidence to support their superiority over other agents, and trials between NSAIDs have shown no apparent difference in efficacy. For acute attacks, indomethacin is typically given at 50 mg three times a day, naproxen at 500 mg twice a day, and ibuprofen at 800 mg three or four times a day. If NSAID therapy is initiated promptly, relief occurs rapidly in the first 24 hours. Treatment should continue for another 24 hours after the symptoms abate and be tapered quickly; durations up to a week may be necessary if initiation of treatment is delayed.

**Colchicine.** Colchicine inhibits microtubule formation and impedes the inflammatory response to the presence of crystals in synovial fluid. Its use for gout predates the foundation of the U.S. Food and Drug Administration (FDA) in 1938 and new trials for safety and efficacy were undertaken to earn government-sanctioned exclusivity.22 Oral colchicine has been shown to be effective for gout in small randomized placebo-controlled trials at a loading dose of 1 mg followed by 0.5 mg orally every 2 hours, or a regimen of 4.8 mg administered across 6 hours.23 However, patients studied with colchicine at these doses eventually had gas, nausea, vomiting, or diarrhea. In 2010, a prospective double-blind study of an oral loading dose of 1.2 mg colchicine followed by 0.6 mg an hour later demonstrated superior pain relief of colchicine over placebo, with a lower incidence of gastrointestinal (GI) complaints compared to other regimens.24 Lower dosing is recommended in elders; in several case reports, dosing of colchicine at 0.6 mg spread over three times a day has been effective for pain relief as well.25 Colchicine is also effective in relieving symptoms from other crystal arthritides and therefore is not helpful when it is used for diagnostic purposes.26

**Adrenocorticotropic Hormone (Corticotropin).** Although it is not commonly used (or studied) because of its expense and lack of general availability, synthetic ACTH is a desirable alternative to the preceding agents because of its rapid onset of action and decreased toxicity in older patients. American College of Rheumatology (ACR) Guidelines for gout management now endorse 25–40 IU ACTH subcutaneously as an appropriate alternative for nil per os (NPO) patients.27

**Other Agents.** Guidelines for management of acute gout recommend that if the flare occurs while a patient is receiving a diuretic, the diuretic should be stopped if at all possible.28 Narcotic analgesics and either local or regional anesthetic blocks are potential adjunctive therapy. Ice has been shown to be a useful adjunctive therapy.29 Rest and elevation may be helpful as well.

**Summary.** Both NSAIDs and colchicine are considered first-line therapies for gout; the two are often used in tandem in patients without contraindications, such as renal insufficiency. Best available evidence supports a treatment strategy of prompt initiation of NSAID therapy (eg, 50 mg of indomethacin three times daily or 500 mg of naproxen twice daily) or colchicine 1.2 mg followed by a 0.6-mg dose an hour later. Patients for whom NSAIDs or colchicine is contraindicated can be treated with intra-articular injections of triamcinolone or ACTH (corticotropin). Systemic steroids, although commonly used, have a weaker evidence base, but one trial suggests that prednisolone 35 mg/day is comparable to naproxen 500 mg twice a day during the course of 4 days.

Follow-up, preferably with a rheumatologist, is recommended for proper prophylaxis against future flares.

**Calcium Pyrophosphate Dihydrate Deposition Disease (Pseudogout)**

**Principles.** Calcium pyrophosphate dihydrate deposition disease (CPPD) results when calcium complex crystals form
Basic Calcium Phosphate Hydroxyapatite Crystal Disease

A variant form of crystalline disease results from basic calcium phosphate (BCP) hydroxyapatite deposits. BCP deposition in synovial fluid is more difficult to detect with light microscopy and is more rapidly progressive and destructive than CPPD.\(^\text{30}\) BCP arthropathy also is manifested with calcific tendinitis, calcific bursitis, and a “pseudopodagra” of the first MTP joint in young women. The Milwaukee shoulder syndrome is characterized by severe bilateral osteoarthritis of the glenohumeral joint, rapid destruction of the rotator cuff, and BCP crystals, leading to joint instability and upward subluxation.\(^\text{31}\) NSAIDs, systemic and intra-articular steroids are typically cited as conventional therapy, without much supporting evidence. For refractory joint pain, a case series supports the use of aspiration and lavage.

Acute Calcific Periarthritis

Acute calcific periarthritis results when amorphous calcium hydroxyapatite deposits extravasate into periarticular soft tissue, causing a self-limited, crystal-induced inflammatory reaction.\(^\text{32}\) It usually occurs in women and most commonly involves the hand or rotator cuff; the symptoms last less than a week, and the radiographic findings resolve about 3 weeks. NSAIDs and steroids are recommended without clinical trial data; a randomized controlled trial suggests that extracorporeal shock wave therapy works for refractory cases.\(^\text{33}\)

Trauma and Hemarthrosis

Trauma is a common cause of acute monoarticular effusion. One prospective series of tense knee hemarthrosis presenting within 12 hours of injury identified complete or partial anterior cruciate ligament tears in 70% of patients and meniscal tears in 16%; synovial disruption was presumed responsible in 5% with another series of acute trauma patients with normal radiographs and hemarthrosis seen on aspiration also showing serious pathologic injuries, such as anterior cruciate ligament, posterior cruciate ligament, or collateral ligament tears after prompt arthroscopy. The authors recommended aspiration of a tense traumatic effusion and urgent arthroscopy.

Chronic Monoarticular Arthritis

Osteoarthritis (Degenerative Joint Disease)

**Principles.** Osteoarthritis, or degenerative joint disease, is the most common form of arthritis among adults, especially in elderly and overweight patients. Mechanical signaling in cartilage mediates chondrocyte production of extracellular matrix molecules. Perturbations in loading (from trauma or excess weight), combined with biochemical and genetic factors, influence cytokine signaling and matrix composition, ultimately causing subchondral bone overgrowth, cartilage degradation, and synovial membrane inflammation.

**Clinical Features.** Patients with osteoarthritis classically describe pain that worsens with activity and improves with rest. The lack of systemic symptoms also helps distinguish osteoarthritis from rheumatoid arthritis. Osteophytic spurs (Bouchard’s and Heberden’s nodes in the PIP and DIP joints, respectively) may be palpated. Affected joints may display crepitus on active and passive ranging.

Radiographs classically show asymmetrical joint space narrowing, although the degree of narrowing often does not correlate with the patient’s perception of pain. Radiographs may also show osteophyte formation at joint margins and subchondral cysts.
Synovial fluid is difficult to aspirate in osteoarthritis but classically is noninflammatory, with fewer than 2000 cells/mm^3 and few PMN cells.

**Management**

**Nonpharmacologic Therapy.** Many nonpharmacologic therapies for knee and hip osteoarthritis have been endorsed through clinical guidelines and meta-analyses, such as weight loss, exercise, patient education, and wedge-soled shoes. For the hand, orthotics and splints are also endorsed, with support from prospective trial data.32,33

**Pharmacologic Therapy.** Acetaminophen at 4 g/day is supported by a systematic review of 15 trials, showing superiority to placebo, although inferiority to NSAIDs for the hip and knee. However, because the adverse effects of acetaminophen are milder and less likely than with NSAIDs, acetaminophen is considered a first-line therapy in guidelines from the European League Against Rheumatism (EULAR) and the American College of Rheumatology.34

Cyclooxygenase 2 inhibitors (eg, celecoxib) are associated with less GI bleeding risk than traditional NSAIDs in randomized trials, with the same apparent effectiveness. However, subsequent concerns for increased cardiovascular toxicity have limited their use. A systematic review of 34 trials (most comparing four times daily topical diclofenac solution and gel to placebo) found the number needed to treat (NNT) of 6.4 to 11 for 50% osteoarthritis pain relief over 8 to 12 weeks. Other studies suggest similar efficacy between topical and oral NSAIDs, with topical NSAIDs showing fewer GI adverse events but more (mostly mild) skin reactions.35

Capsaicin is another low-toxicity topical agent that may help—particularly for hand osteoarthritis pain.36 Opioid analgesics for osteoarthritis pain are supported by a meta-analysis for pain reduction and functional improvement; however, substantial attrition due to adverse effects of opioids limits the validity of the meta-analysis. Therapies involving glucosamine and chondroitin have shown variable benefit. A network meta-analysis revealed no clinically significant improvement with these drugs, alone or in combination, compared with placebo.37

Intra-articular glucocorticoid injections, such as triamcinolone, have shown pain relief lasting months but uneven efficacy in various joints and no measurable effect on physical function. The dose of triamcinolone is generally 10 mg for hand joints; 20 mg for elbows, ankles, and acromioclavicular joints; and 40 mg for knees, hips and shoulders. Intra-articular hyaluronic acid injections have demonstrated some improvement in physical function and superior pain relief compared with intra-articular steroid injections (although apparent only after a period of many weeks to months).

Many clinicians instill amide analogs (such as, lidocaine or bupivacaine) with intra-articular steroid or hyaluronic acid injections to produce a more rapid onset of pain relief. Recently, chondrolysis and cartilage destruction have been reported after amide analogic pain pumps were employed postoperatively.38 Prospective animal trials have shown chondrotoxic effects of lidocaine and bupivacaine after even a single amide injection, although damage from single intra-articular injection of amide analogics in humans has not been reported.39

**Summary.** ED management of osteoarthritis is symptomatic relief. Acetaminophen 4 g/day is supported by many reviews for safety and efficacy. NSAIDs and opioids have shown superiority to acetaminophen for particular kinds of osteoarthritis, but concern for adverse events has limited their application. Topical NSAIDs show the same pain relief as systemic NSAIDs with fewer serious adverse events, although comparisons to acetaminophen are lacking. In patients resistant to these therapies, intra-articular injections of triamcinolone have demonstrated pain relief in the long term, depending on the joint, but with no improvement of physical activities.

Emergency clinicians should not fail to recommend proven nonpharmacologic therapies for knee and hip osteoarthritis, such as weight loss, exercise, and wedge-soled shoes, with referral to an orthopedic surgeon for further management.

**Acute Polyarticular Arthritis**

The differential diagnosis of polyarticular arthritis is broader than that of monoarticular arthritis (Fig. 106.5). A useful classification of polyarticular arthritis presentations are distinguishing acute (defined as <6 weeks) from chronic (>6 weeks). The acute polyarticular presentations include gonococcal arthritis, viral arthritis (eg, rubella, hepatitis), Lyme disease, reactive arthritis, and rheumatic fever. Chronic polyarticular presentations are caused by rheumatoid arthritis, systemic lupus erythematosus, scleroderma, psoriatic arthritis, dermatomyositis, and other autoimmune diseases. Alternatively, polyarticular presentations may be classified as symmetrical or asymmetrical. Rheumatoid arthritis and systemic lupus erythematosus tend to be symmetrical, the others asymmetrical. The spondyloarthropathies (ankylosing spondylitis, reactive arthritis, psoriatic arthritis, and the arthropathy of inflammatory bowel disease) involve predominantly larger joints, but psoriatic arthritis affects the small joints of the hands.

Viral arthritides have varied mechanisms of inflammation (Table 106.6) but typically are manifested as an acute, self-limited, nondestructive polyarticular arthritis.36

**Lyme Disease**

**Principles.** *Borrelia burgdorferi* infection causes the multisystem disorder known as Lyme disease, the most common vector-borne illness in the Western world. In the United States, endemic areas for *B. burgdorferi* and its vector tick *Ixodes* include the Northeast, the upper Midwest, and northern California. More than a quarter-million cases have been reported to the CDC since 1992, with approximately 30,000 cases per year in recent years.40

**Clinical Features.** Lyme disease follows a prescribed pattern of early disseminated disease (weeks to months after a tick bite) and late disease (several months to years later). Musculoskeletal manifestations of the early stage, when present, primarily consist of migratory myalgias and arthralgias without objective evidence of actual arthritis or effusions. Arthritis is the most common manifestation of late Lyme disease.41 When it is untreated, 50% to 60% of patients will have frank asymmetrical arthritis within 6 months—most commonly in large joints, particularly the knees. The natural history of Lyme arthritis is intermittent episodes that gradually abate in intensity and frequency during several years, even if it is untreated. Lyme arthritis appears to be autoimmune-mediated rather than a direct result of the spirochetal infection, but early antibiotic therapy clearly reduces its incidence. Lyme arthritis seems to be more prevalent in infections in the United States because the endemic *B. burgdorferi* displays stronger arthritogenic properties than other strains.

**Diagnostic Testing.** The history of a previous tick bite from an endemic area or the classic erythema migrans rash (although often not remembered by the patient) may aid the clinician in suspecting the diagnosis. Patients have minimal joint pain and usually are afebrile despite large joint effusions. Aspirate is inflammatory with PMN cell predominance, but *Borrelia* cannot be cultured from it. The differential diagnosis includes gonococcal arthritis, septic arthritis, ARF, rheumatoid arthritis,
Immunologic and Inflammatory

Acute Rheumatic Fever

Principles. ARF is a systemic disease triggered by a complex hyperimmune response in the weeks after group A streptococcal pharyngitis. Host cellular and humoral response to group A streptococcal infection attacks joint, cardiac, and other tissue, in part through molecular mimicry mechanisms. The incidence of ARF has dramatically declined in recent decades, in part due to transformation of group A streptococcal strains, improvements in hygiene, and widespread antibiotic use; in the United States, incidence is estimated at 2 to 14 per 100,000.

Clinical Features. The clinical diagnosis of ARF is based on the Jones criteria. The presence of two major criteria (polyarthritis, carditis, chorea, erythema marginatum, and/or subcutaneous nodules; Fig. 106.6), or one major criterion and two minor criteria and reactive arthritis. Routine blood testing is nonspecific and unhelpful. Confirmatory diagnosis is by immunoglobulin M and G serologies.

Management. Prophylactic therapy after a tick bite is not generally recommended except for a *Ixodes* attachment of longer than 36 hours in an endemic region; in these cases, a single doxycycline dose of 200 mg is recommended by the Infectious Disease Society of America (IDSA) clinical guidelines. Lyme arthritis can generally be treated with a 4-week oral course of doxycycline, 100 mg twice daily. Doxycycline is preferred for its excellent oral absorption, low cost, and antiinflammatory activity as a matrix metalloproteinase inhibitor. Amoxicillin 500 mg three times daily and cefuroxime axetil 500 mg twice daily are acceptable alternatives. Amoxicillin is used instead of doxycycline for pregnant and lactating women and for children younger than 8 years old. If Lyme disease is diagnosed at the early stage of erythema migrans, only 2 weeks of treatment is recommended. For patients with neurologic or cardiac symptoms, or refractory Lyme arthritis, an infectious disease specialist should be consulted and IV antibiotics considered.

MCP, Metacarpophalangeal; PIP, proximal interphalangeal.

Fig. 106.6. Erythema marginatum in acute rheumatic fever (ARF). The pen mark shows the location of the rash approximately 60 minutes previously. (From Cohen J, Powederly WG: Infectious diseases, ed 2, New York, 2004, Mosby/Elsevier.)

Group A streptococcal infection–related arthritis, typically migratory, occurs in 75% of patients and mostly affects the large joints. The arthritis lasts 2 to 3 days in each joint and 2 to 3 weeks overall; the axial skeleton is spared. Joints appear modestly inflamed, but the pain is disproportionately excruciating to the patient. ARF arthritis responds so dramatically to salicylate or steroid therapy that the diagnosis can become clouded; lack of response should promote an alternative diagnosis. Naproxen was shown to be as effective as aspirin and better tolerated in a randomized trial in children.

For patients not fulfilling Jones criteria, poststreptococcal reactive arthritis (PSRA) is another sterile group A streptococcal infection–related arthritis, with a more additive than migratory course.

Diagnostic Testing. The diagnosis of ARF is largely clinical; laboratory evaluation for suspected ARF is not conducive to ED care. Throat cultures are negative in 75% of patients with systemic manifestations of ARF. Antibody titers to streptolysin O and anti-DNase B may demonstrate antecedent group A streptococcal infection. Synovial aspirate is inflammatory in nature and sterile, with a widely variable synovial WBC count, no crystals, and a negative culture.

Management. Recommended treatment of suspected acute group A streptococcal infection is benzathine penicillin 0.6 to 1.2 million units intramuscularly or 10 days of oral penicillin (or erythromycin if the patient is penicillin-allergic). Long-term prophylactic treatment to prevent recurrences of ARF is provided with either oral or parenteral penicillin or erythromycin. The duration of prophylaxis depends on the age of the patient, the presence of cardiac involvement, the number of previous attacks, and other factors.

Besides antibiotics, ARF treatments were developed well before the era of randomized trials, so their evidentiary basis is suboptimal. High-dose aspirin (50 to 100 mg/kg/day in four daily doses) for 2 to 4 weeks improves the arthritis and fever but not the symptoms of carditis. Smaller studies have suggested a benefit to oral or IM hydrocortisone over aspirin if carditis is present (1 to 2 mg/kg/day, slowly tapered during 2 to 4 weeks).
Chronic Polyarthritis

Rheumatoid Arthritis

**Principles.** Although rheumatoid arthritis is usually considered a chronic and insidious disease, at least 20% of patients have an acute presentation. Rheumatoid arthritis develops in women two to three times more often than in men, with a peak incidence between the fourth and fifth decades of life. Prevalence is between 0.5% and 1% of Western populations and 5% of women by 70 years of age. There appears to be a genetic predisposition forming immune complexes that stimulate PMN cells to release the enzymes that ultimately cause joint destruction. The synovial cells increase dramatically in number and produce even more inflammatory substances. A pannus of granulation tissue is formed that ultimately destroys the joint.

**Clinical Features.** Patients commonly seek care after a prodromal period of fatigue, weakness, and musculoskeletal pain, with or without fevers and weight loss, that may last weeks to months. The patient’s joints begin to swell in a symmetrical and additive pattern, particularly the hands (MCP and PIP joints), wrists, and elbows. Classically, patients describe morning stiffness lasting more than an hour. DIP joints of the fingers are not involved, which helps distinguish rheumatoid arthritis from osteoarthritis, reactive arthritis, and psoriatic arthritis.

Acute presentations may have only warm, tender, swollen joints that may be difficult to distinguish from a viral arthropathy. Tenosynovitis can occur with acute rheumatoid arthritis.

Long-standing changes of rheumatoid arthritis include MCP and PIP joint swelling, ulnar deviation, swan-neck and boutonnière deformities of the hands, and limitation of dorsiflexion of the wrist. Extra-articular complications are seen in half of patients with rheumatoid arthritis and include subcutaneous nodules vasculitis of the skin, pulmonary fibrosis, mononeuritis multiplex, pericarditis, and Sjögren’s and Felty’s syndromes. Long-standing rheumatoid arthritis is associated with atlantoaxial subluxation, as well as with laryngeal deviation, which should be recognized before endotracheal intubation.

**Diagnostic Testing.** The ED evaluation of the patient with suspected rheumatoid arthritis is directed at excluding other causes of arthritis, particularly septic arthritis. However, the definitive diagnosis of rheumatoid arthritis is complicated and involves confirmatory serology and a chronicity of 6 weeks or more. ESR and CRP levels may be elevated but are nonspecific. Rheumatoid factor, an antibody against gamma globulin, is eventually present in approximately 75% to 85% of patients with rheumatoid arthritis, although it is present in only 50% in the first 6 months.

Early radiographic features of rheumatoid arthritis are soft tissue swelling and juxta-articular osteoporosis leading to uniform joint space narrowing (Fig. 106.7). Subluxation with loss of joint alignment is a later finding.

Synovial fluid analysis is helpful to rule out infectious or crystalline processes. Arthrocentesis reveals inflammatory fluid with WBC counts between 4000 and 50,000/mm³ and more PMN cells (75%) than are usually seen with crystal disease.

**Management.** Excessive movement increases inflammation, so the initial treatment for early or mild disease is rest, in combination with antiinflammatory medication. Oral prednisone, 5 to 15 mg daily, can effectively control mild inflammation as a bridge to more advanced therapy in early disease. A systematic review concluded that short-term, low-dose steroids (prednisone 15 mg/day) are significantly more effective than NSAIDs (and placebo) for alleviation of rheumatoid arthritis symptoms. Even as recommendations for early use of disease-modifying antirheumatic drugs (DMARDs) in rheumatoid arthritis have grown stronger, the safety and efficacy of low-dose corticosteroids make it an appropriate first-line therapy in the ED.43

Clinical studies support the efficacy of a combination of methotrexate and a tumor necrosis factor blocker in reducing early disease activity. Combinations of sulfasalazine 1000 mg two or three times daily and hydroxychloroquine 200 to 400 mg/day are commonly prescribed. Although the choice of DMARD is typically left to rheumatologists, emergency clinicians should be familiar with their potentially life-threatening complications (Table 106.7).

**Fig. 106.7.** Rheumatoid arthritis of the wrist, with osseous erosions shown here including triquetrum, pisiform, scaphoid, and radius. There are erosions at the ulnar aspect of the distal radius and the ulnar styloid process secondary to involvement of the inferior radioulnar compartment. Diffuse cartilage loss also is evident in the radiocarpal compartment. (From Firestein GS: Kelley’s textbook of rheumatology, ed 8, Philadelphia, 2008, WB Saunders.)

**Adult-Onset Still’s Disease**

Adult-onset Still’s disease (AOSD) is a rare (1 to 34 cases per million, worldwide) multisystem inflammatory disorder characterized by acute arthritis, characteristic rash, and quotidian or double-quotidian fevers (with the highest temperatures seen in the late afternoon or early evening). The rash is a salmon-colored macular evanescent rash that occurs only with the fever. Manifestations of AOSD include sore throat, myalgias, splenomegaly, hepatitis, and pericarditis. The differential diagnosis includes other acute arthritides (especially rheumatic fever) and other causes of “fever of unknown origin.” Based on retrospective
In lupus erythematosus; TNF, tumor necrosis factor; UTI, urinary tract infection.

The seronegative spondyloarthropathies share the characteristics of sacroiliac involvement, peripheral inflammatory arthropathy, absence of rheumatoid factor, pathologic changes around the enthesis (ligamentous and tendinous insertion into bone), and a genetic component related to the HLA-B27 marker. The most important of these chronic polyarthritid inflammatory diseases are ankylosing spondylitis, reactive arthritis, the arthropathy of inflammatory bowel disease (enteropathic arthritis), and psoriatic arthritis. Whereas some clinical overlap exists, each has its distinctive features.

**Ankylosing Spondylitis**

**Clinical Features.** Patients with ankylosing spondylitis are generally male, younger than 40 years old, with chronic, insidious back discomfort of more than 3 months, with radiologic evidence of sacroiliitis. Uveitis is the most common extra-articular manifestation, but life-threatening aortic root disease can rarely occur. The peripheral joints are involved in up to 30% of patients with enthesopathic involvement, such as plantar fasciitis and Achilles tendinitis. On radiologic examination, there is a symmetrical squaring of the margins of the vertebral bodies and later the development of a “bamboo spine.” MRI changes occur even earlier at the sacroiliac joint.

**Management.** The goals of therapy are to control pain, to decrease inflammation, and to begin physiotherapy and strengthening exercises. Recent literature review and consensus with use of Delphi methodology recommend a trial of at least two NSAIDs for symptomatic patients. As–tumor necrosis factor, sulfasalazine, methotrexate, and monoclonal antibodies are options for more severe disability and pain.

**Reactive Arthritis (Formerly Reiter’s Syndrome)**

**Clinical Features.** Reactive arthritis occurs in genetically susceptible hosts after infection with *Chlamydia trachomatis* in the genitourinary tract or *Salmonella, Shigella, Yersinia, or Campylobacter* organisms in the GI tract. A number of other microorganisms have also been postulated as causative agents.

Reactive arthritis is generally a disease of patients from 20 to 40 years old, in whom arthritis develops 2 to 6 weeks after an episode of urethritis, cervicitis, or dysentery. The syndrome is predominantly polyarticular, asymmetrical, and often additive (Fig. 106.8). The weight-bearing joints of the lower extremities are commonly involved; knees, ankles, and feet, particularly the heels (“lover’s heel;” see Fig. 106.8B). Other physical signs appear early and may disappear as musculoskeletal complaints persist. Patients may have conjunctivitis early in the disease, which may progress to uveitis. Up to 10% of patients have initially painless lesions of the oral mucosa and tongue that later develop into shallow painful ulcers. Similar lesions are seen on the glans penis (balanitis cincta), particularly in uncircumcised men (20% of patients). Fingers and toes may swell and appear sausage-like, a phenomenon that also occurs in psoriatic arthritis.

Synovial fluid aspirate is inflammatory in nature with a predominance of PMN cells. *Chlamydia, Salmonella, and Yersinia* antigens have been found in the synovial membrane and even in the joint fluid, but cultures are sterile. Early x-ray films show an enthesis where ligaments attach to bone that occurs at the sacroiliac joints, ischial tuberosities, greater trochanter, and Achilles insertion. Patients may have a single episode (the mean length of an episode is 4 to 7 months) or recurrent episodes of arthritis or a continuous spectrum of disease generally involving the ankles and calcaneus.

**Management.** Patients with reactive arthritis respond well to NSAIDs, particularly indomethacin, up to 200 mg/day. Antibiotics improve recovery time for patients with *Chlamydia*-triggered reactive arthritis; no benefit has been found for arthritis with a GI cause.

**Enteropathic Arthritis.** Up to 46% of patients with inflammatory bowel disease experience musculoskeletal manifestations studies showing poor symptomatic control, NSAIDs (such as, indomethacin 150 to 250 mg/day) should only be considered as supportive therapy during the diagnostic process. Corticosteroids (prednisone 0.5 to 1 mg/kg/day) were more effective in symptom relief. Specialists may consider DMARDs, IV immunoglobulin, and biologic agents.65

**Relapsing Polychondritis**

Relapsing polychondritis, a rare multisystem disorder of unknown etiology, is manifested with recurrent severe inflammation of joints, sclera, ears, nose, and vessels of the heart and kidneys. Most patients eventually have unilateral or bilateral external ear swelling and redness. Because of the rarity of this disorder, there are no controlled trials of therapies, although prednisone 0.5 to 1 mg/kg/day and dapsone 50 to 200 mg/day are recommended.66 In some series, flare-ups responded well to colchicine (0.6 mg twice daily). However, tracheobronchial cartilage inflammation is possible and can be precipitous, causing respiratory distress and airway compromise. For this, pulse-dose steroids (1 g/day), racemic epinephrine, and sometimes stenting are recommended.

oligoarthropathy (with sausage digits), symmetrical polyarthropathy, spondylitis (asymmetrical as in reactive arthritis), DIP joint involvement, and arthritis mutilans (Fig. 106.9). Although few trials have been performed on psoriatic arthritis, a recent EULAR consensus statement, derived from trials involving rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis, recommended NSAIDs as first-line therapy. Local glucocorticoid injections may be considered as an adjunct, but systemic steroids lack supporting evidence. Early involvement from rheumatology and escalation to DMARDs has been shown to improve outcomes, although it may take months for a flare-up to subside.

Psoriatic Arthritis. Psoriatic arthropathy occurs in up to 20% of patients with psoriasis. Several forms exist: asymmetrical oligoarthropathy (with sausage digits), symmetrical polyarthropathy, spondylitis (asymmetrical as in reactive arthritis), DIP joint involvement, and arthritis mutilans (Fig. 106.9). Although few trials have been performed on psoriatic arthritis, a recent EULAR consensus statement, derived from trials involving rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis, recommended NSAIDs as first-line therapy. Local glucocorticoid injections may be considered as an adjunct, but systemic steroids lack supporting evidence. Early involvement from rheumatology and escalation to DMARDs has been shown to improve outcomes, although it may take months for a flare-up to subside.

**Fig. 106.8.** Radiographic findings of the foot in reactive arthritis. **A,** Anteroposterior view of the foot reveals erosions and bone proliferation of the first through fourth metatarsophalangeal (MTP) joints with subluxation. Fluffy bone proliferation is noted along the medial malleolus, midfoot, and sesamoid bones of the first metatarsal head (arrows). **B,** Lateral view of the hindfoot shows ill-defined plantar calcaneal enthesophytes (arrowhead), periosteal new bone formation along the posterior aspect of the distal tibia (arrow), retrocalcaneal bursitis and thickening of the Achilles tendon (star), and erosions at the subjacent calcaneus. (From Firestein GS: Kelley’s textbook of rheumatology, ed 8, Philadelphia, 2008, WB Saunders.)

**Fig. 106.9.** Psoriatic arthritis. Note the asymmetry of the distal interphalangeal (DIP) joint involvement and the associated psoriatic nail disease. (From Firestein GS: Kelley’s textbook of rheumatology, ed 8, Philadelphia, 2008, WB Saunders.)
Fibromyalgia

Clinical Features. Patients with fibromyalgia commonly present to the ED with diffuse musculoskeletal pain. The encounter may be unsatisfying for both patient and provider because the disease is ill-defined, there may be suspicion of analgesic abuse, and psychiatric comorbidity is common. Current thinking about the pathophysiologic mechanism of this disorder hypothesizes that the patients process normal pain stimuli aberrantly. Patients with fibromyalgia have a history of 3 or more months of idiopathic, widespread pain (bilateral, upper and lower body, and spine), and an examination showing excessive tenderness of 11 of 18 specific muscle-tendon sites. The differential diagnosis includes the other rheumatic diseases, hypothyroidism, and depression, and more extensive evaluation should be considered with symptoms of short duration. Fibromyalgia is not consistent with the presence of synovitis, fever, or neurologic deficits.

Management. ED management includes ruling out associated diseases, provision of empathy and education, a recommendation for exercise (found to raise the pain threshold and improve symptoms) and referral of the patient to a provider experienced in chronic pain management. For patients in significant distress, initiating drug monotherapy may be considered. Low-dose tricyclic antidepressants (such as, amitriptyline 10 mg once daily at bedtime), selective serotonin reuptake inhibitors, and pregabalin have been shown to improve pain measures and sleep in patients with fibromyalgia. Opioid medications are of no value for fibromyalgia.

Polymyalgia Rheumatica

Polymyalgia rheumatica is manifested with symmetric musculoskeletal aching and morning stiffness of several weeks’ duration, especially of the shoulder and pelvic girdle, almost always in persons older than 50 years old.

Physical signs are modest. An elevated ESR can be used to screen for an inflammatory arthritis; a prospective trial showed the vast majority of polymyalgia rheumatica cases feature an ESR >40 mm, with many above 100 mm/hr. CRP values above 10 mg/L are also suggestive of clinically significant inflammation, although scleroderma, polymyositis, and dermatomyositis are not accompanied by CRP elevation.

Polymyalgia rheumatica is usually self-limited, and a systematic review suggested most patients will respond to low-dose prednisone (15 mg/day or less). All patients should be referred for further evaluation, steroid taper, and evaluation for progression to giant cell arteritis, a closely related disorder.

Scleroderma (Systemic Sclerosis)

Scleroderma has many manifestations discussed in other chapters; musculoskeletal manifestations of scleroderma include morning joint stiffness, tendon friction rubs, symmetrical arthralgias and arthritis, sclerodactyly, and Raynaud’s phenomenon. Although there are no prospective trials of therapy, the arthritis of systemic sclerosis seems generally responsive to treatment borrowed from rheumatoid arthritis, including NSAIDs and steroids.

Disposition

Whereas the majority of emergency presentations for arthritis can be followed up satisfactorily in the outpatient setting, the challenge for emergency clinicians evaluating acute arthritis is to decide which presentations could lead to rapidly progressive disease and potential disability, and merit further evaluation and early treatment.

Patients diagnosed with nongonococcal septic arthritis, on the basis of a positive result of Gram’s stain or culture or a strong clinical suspicion in the face of a negative Gram’s stain result, are admitted for parenteral antibiotics and evaluation for possible arthroscopy or arthrotomy. Patients in whom a disseminated gonococcal infection is suspected are hospitalized for parenteral antibiotics and orthopedic consultation, except in cases in which the patient is well appearing, the symptoms are mild, and the patient is able to comply with the daily follow-up plans. Patients with noninfectious causes of arthritis can be discharged, assuming their pain is controlled and appropriate follow-up can be arranged.

Key Concepts

- The most likely cause of emergency arthritis presentations can usually be identified by considering the number of joints involved (monarticular versus polyarticular), the distribution of joint involvement (large versus small joints and symmetrical versus asymmetrical joint involvement), and the time course.
- The possibility of septic arthritis should be considered in all patients who present with acute monarticular arthritis.
- There is no combination of examination findings or blood tests that places septic arthritis below the threshold for performance of arthrocentesis in adult patients presenting with a new, hot, swollen, painful joint. Synovial fluid analysis is necessary to for risk stratification of septic arthritis, and delays in treatment worsen outcomes.
- The presence of crystals in synovial fluid or a negative Gram’s stain result does not completely eliminate the possibility of septic arthritis. Bacterial arthritis can coexist with gout or pseudogout, and the result of Gram’s stain is positive in only 50% to 80% of cases of septic arthritis.
- Many other common arthritides, such as gout, rheumatoid arthritis, and osteoarthritis, can be managed with NSAIDs as a first-line therapy. In those who cannot tolerate or have not improved with NSAIDs, systemic or intra-articular steroid therapy has been shown to have varying levels of support. Appropriate follow-up is crucial for prophylaxis against future flare-ups.

CHAPTER 106: QUESTIONS & ANSWERS

106.1. Which of the following typically presents with a monoarticular arthritis pattern? A. Drug-induced arthritis B. Gonococcal arthritis C. Pseudogout D. Reiter’s syndrome E. Rheumatic fever Answer: C. Other monoarticular processes are gout, septic arthritis, Charcot’s joint, and hemarthrosis.

106.2. Which of the following typically presents with an asymmetrical polyarticular arthritis pattern? A. Gonococcal arthritis B. Lyme C. Systemic lupus erythematosus D. Viral arthritis E. All of the above Answer: E. Acute rheumatic fever (ARF) does also.

106.3. You perform arthrocentesis of a knee joint because of concern for septic arthritis. Which of the following
findings from joint fluid aspiration increase the likelihood of septic arthritis?
A. Synovial lactate dehydrogenase (LDH) of 300 U/L
B. Synovial lactate of 3.0 mmol/L
C. Synovial white blood cell (WBC) count of 12,000 cells/mm3
D. Viscous aspirate

Answer: B. Synovial LDH levels above 250 U/L are sensitive for septic arthritis, whereas lower levels seem to exclude the diagnosis. Similarly, synovial lactate above 5.6 mmol/L is associated with higher likelihood for septic arthritis. Higher synovial WBC counts are directly proportional to the likelihood of a septic joint, but 12,000 cells/mm3 is still on the low end of the spectrum.

106.4. A 53-year-old man presents with acute onset of right knee pain and swelling. He has a history of diabetes, hypertension, and gout. Physical examination is remarkable for a temperature of 39.6°C and a significant right knee effusion with warmth and significant tenderness to palpitation and motion. Arthrocentesis yields a modestly turbid fluid with a white blood cell (WBC) count of 47,000 cells/mm3 (mostly polymorphonuclear [PMN] cells), few urate crystals, and negative Gram’s stain. Serum erythrocyte sedimentation rate (ESR) is 63 mm/hr. What should be the next step in this patient’s management?
A. Admission for observation and analgesics
B. Intravenous (IV) antibiotics and orthopedics consult for admission
C. Outpatient clindamycin, hydrocodone, indomethacin
D. Outpatient colchicine, ice, elevation, hydrocodone
E. Outpatient ice, elevation, hydrocodone, indomethacin

Answer: B. Differentiation of septic arthritis from a flare of a known inflammatory arthritis is difficult because the two can occur in synchrony. Joint fluid WBC counts may be low or high in either, with even WBC counts of 25,000 having an odds ratio for infection of 0.3. There is a predominance of PMN neutrophils in both. With septic arthritis, Gram’s stain is positive in only 50% to 70% of cases, so ultimately neither WBC or Gram’s stain can rule out a case. Fever is likewise present in both circumstances. In this patient with diabetes and a chronically abnormal joint, definitive management involves obtaining synovial fluid cultures which should be diagnostic.

106.5. A 54-year-old postmenopausal woman presents with acute onset of right ankle pain. She denies injury or preceding illness. Her past history is remarkable for obesity, nephrolithiasis (one episode), and hypertension that is controlled by a thiazide diuretic. Her examination is remarkable for a low-grade temperature and a tender, warm right ankle effusion requiring use of a wheelchair. Which of the following statements regarding this patient’s condition is true?
A. A radiograph will be diagnostic.
B. A response to colchicine is diagnostic.
C. Corticosteroids may be useful.
D. Her uric acid level will likely be elevated.
E. Indomethacin has unique efficacy for this process.

Answer: C. Gout develops in men and postmenopausal women. Most patients probably had chronically elevated uric acid levels for years before clinical gout and may have had renal stones or musculoskeletal problems due to urate disposition. Uric acid levels may actually normalize during acute attacks and are of no benefit (like radiographs). Both gout and pseudogout (also a crystalline deposition disease) respond to colchicines via similar mechanisms. Indomethacin is no better than any other nonsteroidal antiinflammatory drug (NSAID). Corticosteroids may be particularly useful in cases in which renal or gastrointestinal (GI) considerations contraindicate colchicines and/or NSAIDs. A common regimen is corticosterone (adrenocorticotropic hormone [ACTH]) 40 to 80 international units intramuscularly as a single dose.

106.6. Which of the following findings is consistent with osteoarthritis?
A. Lack of hand involvement
B. Morning stiffness lasting 2 or 3 hours
C. Subchondral bone cysts on radiographs
D. Systemic symptoms
E. Synovial white blood cell (WBC) count greater than 2000 cells/mm3

Answer: C. This is seen along with osteophytes and joint space narrowing. Systemic symptoms and prolonged morning stiffness suggest rheumatoid arthritis. Synovial WBC count is generally less than 2000 cells/mm3. Symmetrical and sometimes isolated/severe hand involvement at the proximal interphalangeal (PIP) joint (Bouchard’s nodes) and distal interphalangeal (DIP) joint (Heberden’s nodes) may be seen.

106.7. A 34-year-old man presents with complaints of bilateral knee swelling. He describes several weeks of diffuse transient migratory myalgias and arthralgias with mild generalized fatigue. During the past 10 days, he developed swelling in his right knee to a greater extent than the left. He has no past medical history and normally takes no medications. He does not recall a rash. He does not use alcohol or tobacco and works as a park ranger. Physical examination reveals bilateral large knee effusions. Which of the following statements regarding this patient’s condition is true?
A. Careful inspection should reveal a rash.
B. Fever is expected.
C. Immunoglobulin M and G studies are indicated.
D. Joint pain parallels the size of the effusions.
E. Synovial fluid cultures should be diagnostic.

Answer: C. Lyme disease presents in an insidious manner. The classic rash (erythema migrans) often goes unnoticed. This is followed by a pattern of migratory myalgias and arthralgias. Joint effusions are large, not very painful, and culture negative because of the difficulty culturing Borrelia species.

106.8. A 47-year-old woman presents with fatigue and joint pain. She describes a 3-month history of fatigue, morning stiffness, and bilateral hand, foot, and elbow stiffness that improves somewhat over the course of the day. Laboratory evaluation reveals a normocytic anemia with a white blood cell (WBC) count of 11,300 cells/mm3. She localizes most of her daily pain to the knuckles of both hands. Which of the following statements regarding this patient’s condition is true?
A. Acute pericarditis only occurs after long-standing disease.
B. C1 to C2 instability is unlikely.
C. Finger distal interphalangeal (DIP) joints should reveal painful swelling.
D. The joint pain is typically migratory.
E. The presence of foot pain is not expected.

Answer: B. This presentation for rheumatoid arthritis is fairly typical. C1 to C2 instability due to transverse ligament degeneration is only after long-standing disease. Pericarditis, however, may occur as an acute presentation or chronically. More than 90% of rheumatoid arthritis patients develop foot pain, classically in the first and fifth metatarsophalangeal (MTP) joints. The joint pain is progressive and additive—not migratory.
CHAPTER 107

Tendinopathy and Bursitis

Christopher Hogreve | Emily Martin Jones

TENDINOPATHY

Principles

Background

Emergency clinicians may see a wide variety of patients with tendinopathies due to overuse and injury due to growing involvement in athletics and fitness-related activities and overall increased participation by individuals at younger ages. Approximately half of all sports participants will be injured at some time, and of these injuries, up to half will involve tendinopathy. Tendinopathies have been implicated in approximately 40% of tennis injuries, and up to 79% of runners will sustain an injury during a given year, with most of these injuries related to overuse. Overall, women younger than 30 years old are at the greatest risk for overuse injuries. In the workplace, the incidence of work-related musculoskeletal disorders is higher in occupations that involve repetitive motion, localized contact stress, awkward positions, vibrations, and forceful exertion. Additionally, those working for 25 to 35 years are 7.1 times more likely to develop tendinopathy. Ergonomic and medical intervention programs may reduce the incidence of work-related injuries.

Complicating the acute pain and functional limitations, tendinopathies often become chronic (greater than 3 months in duration) and can be disabling. Patients may have symptoms for extended periods despite appropriate therapy. The management of tendinopathy focuses on identifying the cause of discomfort; eliminating the sources of primary tendinopathy; instituting treatment modalities, such as analgesic medication, protection, relative rest, optimal loading, application of ice, compression, and elevation as necessary; modifying behavior to minimize or eliminate sources of continuing irritation; and, importantly, referring patients for appropriate follow-up care and early rehabilitation. However, despite these interventions, recurrence of the tendinopathy is common.

Tendons are collagenous structures that connect muscle to bone. They transmit forces originating in the muscle to the bone, enabling joint motion. The diagnosis of tendinitis, a commonly used term implying “inflammation of the tendon,” has long been attached to many overuse injuries. Many practitioners now advocate use of the term tendinosis as a more accurate reflection of the pathologic process, representing a degenerative process without evidence of inflammation. Although it has been noted that reliable, well-conducted epidemiologic studies have not been performed for most tendinopathies, the histopathologic substratum, in many cases, is degenerative. The term tendinopathy is used throughout this chapter to refer to a painful, impaired tendon, encompassing the variety of pathologic processes.

Mechanical overload and repetitive microtrauma to the musculotendinous unit are thought to be the major precipitating causes of most tendinopathies. This is a result of extrinsic and intrinsic factors that modify the pathophysiologic state. Intrinsic factors (eg, age, gender, blood type O, malalignment, joint laxity, muscle weakness, and imbalance) can result in excessively high or frequent mechanical loads during normal activity. Extrinsic factors (eg, ergonomics, equipment changes, abnormal movements, excessive duration of activity, and increased frequency or intensity of activity) can also contribute to the development of a tendinopathy. Other potential contributing etiologies include excessive protein intake, obesity, systemic disease, and medication use. An increased incidence of tendinopathy and tendon rupture, particularly of the Achilles tendon, is reported in patients taking fluoroquinolone antibiotics. This risk is further increased within the first month of treatment, in those over 60, patients receiving steroid treatment, or those with renal disease. Most tendinopathies have a multifactorial origin. Several of the common areas affected by tendinopathy are found in Figure 107.1.

Under optimal conditions, such as appropriately graduated athletic training, the musculotendinous units are able to adapt to tension overload. This is secondary to the ability of bone to increase its load-bearing capacity along with an increase in size and strength generated by the hypertrophy of existing muscle fibers. An enhancement of tendon and ligament strength occurs by an increase in collagen content, collagen cross-linking, and mucopolysaccharide content. Unfortunately, many athletes may not allot sufficient time for this adaptive process to occur. For instance, a runner may increase mileage, intensity, or both with haste, not allowing for the cellular changes that are required to adapt to the increased stresses. Poor technique, suboptimal running surfaces or environmental conditions, and improper equipment may also contribute to the development of an overuse syndrome.

Pathophysiology

The pathophysiologic mechanism of tendon healing has mainly been described in the literature in the context of acute injury (eg, rupture), and correlation to the healing process in tendinopathies remains unclear. Acutely injured tendons go through several stages in the healing process, which are thought to involve cell proliferation, collagen disorganization, increased proteoglycans, and neo-vascularization. It may take 6 to 12 weeks for the tendon to regain its former strength. As the healing process ensues, unrestricted activity is generally avoided. However, atrophy associated with immobilization should also be avoided because the strength in healing tendons and ligaments increases faster when controlled forces are applied. Consequently, optimal loading is now advocated as a means of advancing from rest to a balanced, incremental rehabilitation program. Such rehabilitation focuses on flexibility forces, eccentric strength training, and a measured return to resistive exercises as long as pain is not produced. Most patients with overuse tendinopathies fully recover within 3 to 6 months. In summary, a prescription for good follow-up with proper rehabilitation is important in the treatment of tendinopathies.

Clinical Features

General Tendinopathy

The history of the patient presenting with a tendinopathy can be variable, although certain clinical aspects are characteristic. A
In the evaluation of the patient with a tendinopathy, a thorough, directed musculoskeletal examination yields important information. Searching for signs of edema, effusion, erythema, atrophy, deformity, asymmetry, or trauma can be helpful. Palpation of the tendon, noting warmth or evidence of crepitance on movement, is important. Evidence of tenderness over the tendon, especially localized and reproducing the patient’s pain, should be elicited. However, although tendon palpation can be sensitive for reproducing tendinopathy-related symptoms, it is not particularly specific in determining the pathologic structure. Underlying bone tenderness (and consideration of other differential diagnoses, including avulsion fracture and osteomyelitis; Box 107.1) should be assessed as well. Motor function (particularly passive and active range of motion), strength (and evidence of weakness or pain), and joint involvement and stability should be noted.

In narrowing the diagnosis, it is important to determine whether the source of pain is articular (within the joint capsule) or periarticular (around the joint capsule). In general, arthritis produces generalized joint pain, warmth, swelling, and diffuse tenderness. The discomfort of arthritis increases with both passive and active motion of the joint. In contrast, the pain of a tendinopathy tends to be more localized. Tenderness and swelling do not occur uniformly across the joint, and pain may be produced only with certain movements, particularly with resisted active contraction or passive stretching of the affected muscles or tendons. However, the diagnostic significance of mechanical hyperalgesia (ie, increased pain with passive and active range of

recent history of repetitive stress may be reported due to work activities, changes in the workplace, or alterations in sport or recreational activities. It is important to ask patients to consider the weeks to months preceding the onset of symptoms: a potential inciting event or change (eg, workplace ergonomics, protective footwear, new sports equipment, and so on) may be elicited. Occasionally, no cause is identified for a mechanical overload. A history of fluoroquinolone therapy, infectious disease, or other systemic illness should also be obtained as initial presentations of rheumatologic disorders or infections, such as those from Mycobacterium, have been described.

Pain is the most common symptom of the patient who presents with tendinopathy. Increasing, non-radiating discomfort at the site of the affected tendon is a general symptom. The discomfort is frequently described as more severe subsequent to periods of rest. Unlike the discomfort of morning stiffness associated with arthritis, the pain of tendinopathy may resolve after initial movement, only to be manifested as a throbbing pain after the completion of exercise. Individuals may report similar prior episodes, whereas continued episodes may be accompanied by an increased severity in pain. Consequently, it may be helpful to inquire about a related previous diagnosis, how it was made, and which treatment (if any) was effective in resolving the prior episode.

In narrowing the diagnosis, it is important to determine whether the source of pain is articular (within the joint capsule) or periarticular (around the joint capsule). In general, arthritis produces generalized joint pain, warmth, swelling, and diffuse tenderness. The discomfort of arthritis increases with both passive and active motion of the joint. In contrast, the pain of a tendinopathy tends to be more localized. Tenderness and swelling do not occur uniformly across the joint, and pain may be produced only with certain movements, particularly with resisted active contraction or passive stretching of the affected muscles or tendons. However, the diagnostic significance of mechanical hyperalgesia (ie, increased pain with passive and active range of
motion) is controversial because its presence may reduce the specificity of the commonly used clinical tests discussed later in this chapter. 7

### Specific Tendinopathies

**Shoulder.** Tendinopathies of the shoulder joint include impingement syndrome (which includes subacromial bursitis or rotator cuff tendinopathy), bicipital tendinopathy, calcific tendinopathy, and adhesive capsulitis.

**Impingement Syndrome and Rotator Cuff Tendinopathies.** The shoulder joint is predisposed to soft tissue injury because of its extensive range of motion and unique anatomic structure. Although it is inherently unstable, the muscles of the rotator cuff (supraspinatus, infraspinatus, teres minor, and subscapularis) and the glenohumeral ligaments serve to stabilize the joint. The muscles of the rotator cuff originate from the scapula (hence their nomenclature), and their tendinous insertion is found on the fibrous capsule of the glenohumeral joint after traversing through the subacromial space. The presence of the subacromial bursa, as for all bursae, serves to ensure fluidity of movement, but it may become inflamed as a part of an impinge-ment syndrome. Impingement of the tendons occurs because of their position interposed between the humeral head and the acromion, which may predispose to a chronic tendinopathy. The functional arc of the elevated shoulder is forward and in the plane. As a result of this position, the greater tuberosity of the humerus may compress (impinge) the tendons of the rotator cuff (usually the supraspinatus) against the undersurface of the anterior third of the acromion. Additionally, the long head of the biceps may be involved in impingement syndrome due to the location between the supraspinatus and subscapularis tendons in the rotator interval. Development of this tendinopathy may be a result of overuse of the extremity that leads to microtrauma of the tendinous fibers, individual anatomic differences (congenital or from the process of aging, such as osteophytic changes), or both. Other entities that may coexist and complicate an impingement syndrome include subacromial bursitis, bicipital tendinopathy, and calcific tendinopathy.

More than 30 years ago, Neer noted that 95% of rotator cuff tears are associated with impingement (excluding tears due to a one-time traumatic event). He described three progressive stages of the impingement syndrome as a result of overuse. The first stage is frequently seen in athletes younger than 25 years old who participate in sports that require repetitive overhead motions of the shoulder (eg, swimming and baseball). The pain is usually described as a dull ache over the anterolateral shoulder, extending from the shoulder to the middle upper arm, often occurring after an activity involving flexion and abduction of the arm. Point tenderness may be elicited over the greater tuberosity. No weakness or loss of motion is generally present. This condition is generally believed to be reversible with appropriate treatment. In the second stage, as mechanical trauma continues, fibrosis and thickening of the tendon and subacromial bursa may occur. This generally affects patients between 25 and 40 years old. The pain becomes constant and may worsen at night. Active motion may be limited by pain, and any activity involving overhead movement exacerbates the symptoms. Passive range of motion should be preserved, and on physical examination pain is more diffuse and intense. The third stage has symptoms similar to those of the second stage but may involve a prolonged history of shoulder problems. The range of motion of the shoulder is usually decreased because of either disuse or a partial rotator cuff tear. On pathologic examination, tendon degeneration and attrition may be present. Partial-thickness tears may occur or extend with minor trauma or stress. Complete tears of the rotator cuff, biceps tendon rupture, and osteophytic bone changes are sometimes seen.

Physical examination in the evaluation of a rotator cuff tendinopathy includes maneuvers that can exacerbate the symptoms of impingement. Because the supraspinatus tendon is most often involved, a physical examination sign (sometimes referred to as Jobe’s sign, after Frank Jobe, former team physician of the Los Angeles Dodgers, or the empty can test, describing the position of emptying aluminum cans) is helpful in assessing the supraspinatus tendon with resistance testing. With the arms abducted at 90 degrees in the scapular plane (30 degrees anterior to the coronal plane), the arms are internally rotated with the thumbs pointed downward. The examiner places a downward force on the arms, and the patient is instructed to resist the examiner and to keep the arms parallel to the floor. Weakness or pain is considered a positive finding. When assessing for subacromial impingement, the empty can test has a sensitivity of between 50% and 52% with a specificity ranging from 33% to 87%. If the patient is unable to resist the force of the examiner, a supraspinatus tear should be suspected.

Another sign of rotator cuff tendinopathy is elicited by the Neer test, which suggests mechanical impingement with a decrease of the subacromial space. The examiner forward flexes the arm to 180 degrees, which causes impingement of the greater tuberosity of the humerus with the anterior and inferior edge of the acromion. A positive result occurs if there is pain produced at the end range of the arc. Studies assessing the utility of this test report significant variability, with sensitivities ranging from 54% to 81% and specificities from 30% to 95%.

The Hawkins–Kennedy test, also indicative of mechanical impingement, is performed by forcibly internally rotating the proximal humerus while the shoulder is forward flexed to 90 degrees and the elbow flexed to 90 degrees. Pain with this maneuver indicates a positive finding. Again, the sensitivity (58% to 74%) and specificity (40% to 89%) of this test fluctuates in the literature.

A complete rotator cuff tear is evaluated by the drop arm test, in which the arm is passively abducted at 90 degrees and the patient is asked to maintain the abduction. If the arm drops to the side, a large rotator cuff tear should be considered. Studies have shown this test to be 74% sensitive and 66% specific for a full-thickness rotator cuff tear. The shrug sign is exhibited when a patient with acute macrotrauma to the rotator cuff is asked to abduct the arm at 90 degrees and appears to be giving a shrug with that side. This movement results from the scapula’s attempt to abduct the arm without the assistance of the rotator cuff. Although this has historically been associated with rotator cuff disease, it is somewhat nonspecific and can be associated with

### BOX 107.1

**Differential Diagnosis for Tendinopathy**

- Tendon rupture
- Ligamentous injury
- Inflammatory arthritis (eg, rheumatoid)
- Fractures (eg, avulsion)
- Tumors
- Tenosynovitis
- Osteochondrosis (eg, Osgood-Schlatter disease)
- Bursitis
- Septic arthritis
- Osteoarthritis
- Foreign bodies
- Osteomyelitis
- Nerve entrapment syndromes
- Tendon sheath infections (eg, pyogenic)
other shoulder disease, including glenohumeral osteoarthritis and adhesive capsulitis.\textsuperscript{17} Patients with adhesive capsulitis (frozen shoulder) have limitation of active and passive range of motion.

**Bicipital Tendinopathy.** The tendon of the long head of the biceps, given its passage between the supraspinatus and subscapularis tendons in the anterior shoulder, can be associated with impingement syndrome. The patient with bicipital tendinopathy may report pain in the anterior shoulder that radiates down to the radius. Discomfort occurs when the individual rolls onto the shoulder at night or attempts to reach into a pants pocket. Focal tenderness can be obtained by palpation of the groove between the greater and lesser tuberosities of the humerus. However, research has shown that clinician accuracy in palpating the long head of the biceps tendon is poor.\textsuperscript{11} Yergason's sign can assist in the diagnosis of bicipital tendinopathy. This test is performed by having the patient flex the elbow to 90 degrees with the arm against the body and resisting supination of the forearm. Pain in the area of the proximal tendon is considered to be a positive finding and indicative of bicipital tendinopathy. There is significant variability in its sensitivity (14% to 75%), although its specificity is good (78% to 89%).\textsuperscript{10}

Another physical examination tool in the diagnosis of bicipital tendinopathy is the Speed sign. With the elbow extended and the forearm supinated, the patient is instructed to resist forward flexion of the adducted shoulder at 60 degrees. Pain in the area of the proximal biceps tendon (bicipital groove) is indicative of a positive finding. Although this test may be suggestive of labral pathology as well, meta-analyses suggest that it is more sensitive and specific for bicipital tendinopathy.\textsuperscript{10,12}

**Calcific Tendinopathy.** Calcific tendinopathy is an acutely or chronically painful condition associated with the deposition of calcium crystals that occurs in or around the tendons of the rotator cuff. The cause is unknown but has been postulated to be related to tissue hypoxia and degeneration due to overuse. Also, studies have shown an association of calcific tendinopathy with diabetes mellitus and thyroid disorders.\textsuperscript{13} Although it can affect any of the rotator cuff tendons, it seems to have a predilection for the supraspinatus. The symptoms are similar to those of an impingement syndrome, and the condition generally affects people older than 40 years old. Calcium deposition occurs over time and then undergoes spontaneous resorption. This resorptive phase is thought to be the painful aspect, but the severity of the symptoms is not related to the size of the deposit. Pain is believed to be in response to the local chemical pathologic disorder and direct mechanical irritation. On physical examination, there may be specific tenderness over the greater tuberosity, as well as symptoms consistent with impingement. Radiographic evaluation may show evidence of calcification in or around the rotator cuff tendons (Fig. 107.2). The presence of calcium in the tendon does not necessarily affirm the origin of the pain because asymptomatic patients may have evidence of calcification on a routine radiograph.

**Elbow.** Increasingly, athletes of all ages and skill levels are participating in sports involving overhead arm motions. Consequently, the incidence of elbow injuries is increasing.\textsuperscript{14} From an anatomic and functional perspective, the extensors and supinators of the wrist attach to the lateral elbow, and the flexors and pronators attach medially.

**Lateral Epicondylitis.** Lateral epicondylitis ("tennis elbow") is a painful elbow condition that occurs at the insertion of the common extensor tendon (extensor carpi radialis brevis) onto the lateral epicondyle of the humerus. Although it occurs in many tennis players, epidemiologic studies suggest that less than 5% of patients with such a syndrome actually play tennis. Activities such as driving in screws, use of a wrench, and repetitive work on an assembly line have also been implicated. In fact, it has been shown that in such strenuous jobs there is up to an 11% incidence of lateral epicondylitis. Symptoms often begin as a dull ache on the outer (lateral) aspect of the elbow. The discomfort can be exacerbated by activities that involve extension or supination of the wrist, such as grasping and twisting. Cozen’s test is performed by having the patient keep the fist clenched while extending the wrist. The examiner grasps the forearm with the left hand while the right hand pulls the patient’s hand toward flexion against the patient’s resistance. A positive finding is pain at the lateral epicondyle, reproducing the patient’s symptoms.

Active extension of the middle finger (ie, third digit) against resistance with the elbow in extension, which is known as Maudsley’s test, can also reproduce the pain over the lateral epicondyle at the insertion of the extensor carpi radialis brevis. In addition, patients will typically have tenderness to palpation just distal to the lateral epicondyle, over the origin of the extensor carpi radialis brevis.

Radiographs can be helpful in cases with atypical or prolonged symptoms to rule out other pathologic conditions. Approximately 20% of patients demonstrate tendon calcification or a reactive exostosis at the tip of the epicondyle. The differential diagnosis of lateral epicondylitis includes posterior interosseous nerve entrapment (motor aspect of the radial nerve in the forearm), plica lesions, synovitis, chondromalacia, and adolescent osteochondral defects.

**Medial Epicondylitis.** Less common than its lateral counterpart, medial epicondylitis ("pitcher’s elbow” or “golfer’s elbow") can result from microtrauma at the site of the insertion of the flexor carpi radialis on the medial epicondyle. It is important to differentiate medial epicondylitis from other causes of medial elbow pain, including medial ulnar collateral ligament injury. As a result of repetitive valgus stress placed on the joint, microtraumatic injury and valgus instability at the ligament can occur. With disruption of the medial ulnar collateral ligament, abnormal stress is placed on the articular surfaces, which may lead to degenerative changes and the formation of osteophytes. In the case of medial epicondylitis, patients will generally have tenderness over the flexor pronator origin slightly distal and anterior to the medial epicondyle. The pain of medial epicondylitis can be reproduced by having the patient attempt wrist flexion and forearm pronation against resistance.

**Wrist**

**de Quervain’s Tenosynovitis.** The wrist and hand comprise several tendons that pass through thick, fibrous retinacular tunnels. These help prevent subluxation of the tendons and act as
a pulley system. Overuse syndromes are thought to result from changes of the synovial lining between these tendons and the retinaculum. de Quervain's tenosynovitis involves the synovial lining of the abductor pollicis longus and extensor pollicis brevis. Although the term tenosynovitis indicates an inflammation of the tendon sheath, it has been noted that there are many potential forms of tenosynovitis. Classic acute inflammatory changes that are characteristic of tenosynovitis may be related to systemic manifestations of disease (eg, rheumatoid arthritis and gout). Tenosynovitis related to de Quervain's syndrome is referred to by some practitioners as stenosing tenosynovitis. The pathologic process of de Quervain's tenosynovitis does not generally involve inflammation because the primary change is thickening of the extensor retinaculum covering the first dorsal compartment of the wrist. It has been suggested that de Quervain's disease is a result of intrinsic degenerative mechanisms rather than extrinsic inflammatory ones.

The history may consist of chronic, repetitive trauma or uncustomed repetitive efforts, such as firm grasping and movement of the hand in a radial direction. However, studies have not found a causal relationship between this condition and specific occupational risk factors. Direct trauma, such as a direct blow or fall, has occasionally been implicated. Yet, in most cases of de Quervain's tenosynovitis the onset is gradual. The discomfort of de Quervain's tenosynovitis can be localized over the radial styloid process. Radiation of pain proximally to the forearm or distally down the thumb has been noted. The pain is generally constant but may be exacerbated by maneuvers that include grasping, abduction of the thumb, and ulnar deviation of the wrist.

On physical examination, slight swelling may be seen over the radial styloid. Crepitance may be appreciated over the tendons with flexion and extension of the thumb. An increase in the tensile load (passive stretching or active contraction) in the abductor pollicis longus or extensor pollicis brevis increases pain. The Finkelstein test, which exacerbates the discomfort of de Quervain's tenosynovitis, is the most pathognomonic physical sign. The patient is instructed to hold the affected thumb in the palm by the fingers and then to ulnar deviate the wrist. Pain will occur near the radial styloid, which is also the point of tenderness. Pain with this maneuver is considered to be a positive finding. Radiographs are characteristically normal. The differential diagnosis includes scaphoid fracture and osteoarthritis of the carpal metacarpal joint, which features pain caused by longitudinal traction and compression. It should be noted that the Finkelstein test can produce some pain at the carpal metacarpal joint, reducing its specificity. Rarely, infections such as tuberculosis or disseminated gonococcal infections can manifest as tenosynovitis.

Knee

Patellar Tendinopathy. Patellar tendinopathy (“jumper’s knee”) commonly occurs in sports that have a prominent jumping component, although it can also occur as a result of other sporting activities. Patients report pain at the inferior pole of the patella. The discomfort may abate with activity early in the tendinopathy but later progresses to the point of discomfort during both exercise and rest. With the knee flexed at 30 degrees, which relaxes the quadriceps, tenderness may be localized to the deep surface of the proximal attachment of the patellar tendon at the inferior pole of the patella. However, healthy active athletes sometimes have tenderness on examination as well.

The differential diagnosis includes patellofemoral syndrome, which arises from imbalances in the forces that control tracking during knee flexion and extension. The patient usually complains of anterior knee pain, described as “behind” or “around” the patella, which is classically worse with ascending or descending stairs or on rising from a seated position. On occasion, there is tenderness of the medial or lateral retinaculum or facets.

Imaging with ultrasonography and magnetic resonance imaging (MRI) may reflect collagen degeneration or collagen disorganization but is generally adjunctive to the distinctive history and physical examination findings. It is noted that some asymptomatic jumping athletes have imaging appearances similar to those of affected individuals and that prognosis and outcome are not predicted by such imaging.

Ankle

Achilles Tendinopathy. Achilles tendinopathy is a common overuse syndrome that typically affects male athletes. The Achilles tendon is named for the mythological Achilles, whose heel was not immersed in the river Styx as his mother dipped him in the river for its protective powers. It arises from the medial and lateral heads of the gastrocnemius muscle and the deep layers of the soleus muscle, inserting on the calcaneal tuberosity. A major function is plantar flexion of the foot. It is the strongest and largest tendon in the body and can withstand tensile loads more than 12 times the body’s weight during running.

The Achilles tendon is vulnerable to injury from either trauma or overuse. A tendinopathy can also develop as a result of systemic disease (eg, ankylosing spondylitis, Reiter’s syndrome, gout, and pseudogout). The use of fluoroquinolones has also been related to Achilles tendinopathy.

The occurrence of Achilles tendinopathy is highest among individuals who participate in middle- and long-distance running, track and field, tennis, badminton, volleyball, and soccer. Some studies have noted an almost 10% annual incidence of Achilles disorders in elite runners, with lifetime incidence reports up to 52%. The most common Achilles disorders are tendinopathy (55% to 66%) and insertional problems, such as retrocalcaneal bursitis and insertional tendinopathy (20% to 25%). Many cases of Achilles tendinopathy are thought to be multifactorial in origin. Body mechanics and environmental factors (eg, uneven terrain) may apply valgus or varus stress to the tendon. Technique, equipment, and body mechanics can also contribute to the development of this tendinopathy. Anatomically, the vascular supply to the tendon creates a watershed area approximately 2 to 6 cm above the calcaneal insertion. This is thought to be responsible for clinical symptoms and the pathologic disruption commonly seen at this site.

The patient’s history provides most of the information necessary to make the diagnosis of Achilles tendinopathy. Pain, a cardinal symptom of Achilles tendinopathy, may lead the patient to seek medical help. Some practitioners have noted that the patient’s symptoms reflect the degree of the tendon abnormality, which has been validated in MRI studies assessing abnormal signal within the Achilles tendon. However, studies focusing on other changes associated with Achilles tendinopathy, such as neovascularization, have not shown a correlation with pain severity. Regardless, as with many tendinopathies, pain after strenuous activities is reported in the early phase, whereas pain in the later phase occurs during activity and even at rest. At this point, the patient is often unable to perform sporting activities.

On physical examination, inspect the contour of the muscle-tendon unit and note areas of swelling and erythema. In acute Achilles tendinopathy, the tendon may be diffusely swollen and exhibit tenderness on palpation, usually greatest in the middle third. Typically, in the patient who has acute symptoms of tendinopathy, the area of swelling and tenderness does not move with dorsiflexion of the ankle joint. On palpation, local heat, crepitance, and palpable tendon nodules or defects may be noted. Examination for ankle instability and biomechanical faults should be considered.

Achilles Tendon Rupture. Although rupture of the Achilles tendon most often occurs when it is preceded by tendon damage, it is possible for untrained athletes to apply excessive force and to
rupture the tendon in the absence of prior changes of tendinopathy. Partial and complete rupture may occur, most commonly in 30- to 40-year-old men. Complete rupture is more common in the middle-aged recreational athlete. Historically, the patient may note a “pop” followed by acute weakness and an inability to continue with exercise or sport. The patient may report feeling as though he or she was struck in the back of the ankle.

On physical examination, a defect in the tendon can sometimes be palpated. If enough time has elapsed to allow hematoma formation, bogginess may be noted over the injured area of the tendon. The ability to plantar flex the foot does not rule out a complete rupture of the Achilles tendon. There are multiple plantar flexors of the foot and toes. Muscles such as the tibialis posterior, flexor digitorum longus, flexor hallucis longus, peroneus brevis, and peroneus longus can remain functional and therefore disguise a complete rupture with the ability to plantar flex the foot.

A couple of observations that aid in the diagnosis of an Achilles tendon rupture can be made with the patient in the prone position. Assess for decreased resting plantar flexion compared to the opposite side, which is normally 20 degrees to 30 degrees.19 The Thompson (Simmonds) test can also be performed to evaluate for a complete rupture. With the patient prone and feet hanging over the edge of the bed, the examiner squeezes the calf muscles at their widest point and looks for passive plantar flexion. The absence of plantar flexion is considered a positive finding, indicative of a complete tear of the Achilles tendon. The presence of plantar flexion does not, however, eliminate the possibility of a partial tear of the Achilles tendon. Overall, the triad of a palpable tendon defect, decreased resting tension, and a positive Thompson test has a diagnostic sensitivity greater than MRI.19

Differential Diagnosis

The differential diagnosis of tendinopathy is listed in Box 107.1.

Diagnostic Testing

The diagnosis of tendinopathy is generally made on clinical grounds. Although plain radiographs may be helpful in excluding bone abnormalities, ultrasonography has been recommended by some practitioners as the modality of choice for evaluation of pathologic tendon conditions. Ultrasonography can be especially useful when other conditions (e.g., gouty arthritis) obscure the findings of concomitant tendinopathy. Although its efficacy in the hands of emergency clinicians relative to tendon injury is still being studied, it has been shown to be effective in identifying conditions, such as shoulder impingement and tendon disruption or rupture.20-21 In cases of acute or chronic tendinopathy, one or more of the following features can be seen: loss of the fibrillar echotexture, focal tendon thickening, diffuse thickening, focal hypoechoic areas, extended hypoechogenicity, irregular and ill-defined borders, micro ruptures, and peritendinous inflammatory edema. Hypoechoic areas surrounding tendons provide evidence for surrounding soft tissue inflammation. In addition to tendinopathy, tendon tears, both partial and complete, can be delineated by ultrasonography.

MRI has been used to visualize pathologic conditions of the tendon. It is able to provide high intrinsic tissue contrast, which permits the distinction between normal tendons and abnormal tendons, and the high spatial resolution that permits detailed anatomic structures to be identified. MRI has superb resolution of the soft tissue structures and can aid in a variety of tendon disorders. Cost, availability, the need to have the patient remain still during the examination, and the loss of the dynamic component compared with ultrasound examination are disadvantages of this modality.22

Management

General Tendinopathy

The management of tendinopathy focuses on identification of the cause of discomfort; elimination of sources of primary tendinopathy; institution of treatment modalities, such as analgesic medication, protection, relative rest, application of ice, compression, and elevation as necessary; modification of behavior to minimize or to eliminate sources of continuing irritation; and, importantly, referral for appropriate follow-up care.

Cryotherapy (cold treatments, 20 minutes at a time every several hours, for the first 24 to 48 hours) may be beneficial. Nonsteroidal anti-inflammatory drugs (NSAIDs) are also sometimes indicated to provide pain relief, although there is little evidence to support a beneficial effect with their use because tendinopathies tend to represent a degenerative rather than an inflammatory process. Graduated range-of-motion exercises may be useful after the period of immobilization. Although a corticosteroid injection is often used, its role for most tendinopathies is unclear. Most patients will experience short-term improvement in pain and/or function after a corticosteroid injection, but this comes at the expense of a higher risk of relapse in the medium- and long-term. Steroids should not be injected into a major tendon such as the Achilles or patellar tendons, which may be at risk for spontaneous rupture if they are already weakened.

The use of nitroglycerin patches has been shown to be effective in the treatment of tendinopathy. Questions remain as to whether its efficacy is due to an analgesic effect or rather a healing effect on the affected tendon. Studies assessing lateral epicondylitis and Achilles tendinopathy have shown their use to be superior to placebo. Headaches are the most commonly experienced side effect of this medication. The use of this nitroglycerin patches for tendinopathy is off-label and may be considered in follow-up with a sports medicine provider or an orthopedist.

Platelet-rich plasma (PRP) injections, a process by which a patient’s platelets are concentrated in a centrifuge and then injected into the affected tendon, have been introduced as a treatment modality. The literature contains numerous case reports and small studies suggesting this treatment is effective. However, a general lack of high-quality, randomized, prospective controlled trials precludes our recommending its use in the emergency department (ED) at this time.

Specific Tendinopathies

Impingement Syndrome and Rotator Cuff Tendinopathies. The treatment of rotator cuff tendinopathies and the impingement syndrome follows the treatment of tendinopathy in general. Emphasis is placed on physical rehabilitation and strengthening exercises. A significant proportion of patients will improve with conservative management. In those who do not, surgical intervention (such as, acromioplasty, débridement, or repair) may be indicated.23

Calcific Tendinopathy. The initial treatment of calcific tendinopathy is mainly conservative and consists of analgesia and brief sling immobilization because prolonged immobilization may result in adhesive capsulitis. The use of corticosteroids is controversial. Ultrasonography and extracorporeal shock wave therapy have been used with some success. As well as arthroscopic treatment, localized disruption by needle lavage and aspiration under ultrasound-guidance has been shown to be effective with improved pain and function outcomes compared to corticosteroid injections and extracorporeal shock wave therapy.24,25 A small percentage of patients who do not respond to these interventions may need surgery. Follow-up care from the ED is important.
because calcific tendinopathy has been described as the most well-known cause of reactive cuff failure (Fig. 107.3).

Lateral and Medial Epicondylitis. In up to 95% of patients, epicondylitis will improve with conservative therapy. Initial efforts include making the patient more comfortable with the standard principles of protection, relative rest, cryotherapy, compression, elevation, medications (NSAIDs), and modalities of physical therapy. The term relative rest implies the avoidance of overuse as opposed to the absence of activity. Activities that aggravate the pain should be eliminated, and an attempt to protect the tendon through such strategies as a reduction in playing time or intensity should be considered. The use of bracing (eg, counterforce brace) to control force loads, improving performance technique, and the use of appropriate equipment should also be considered. Studies regarding the efficacy of corticosteroid injections suggest a short benefit (at 4 weeks), but worse clinical outcomes at 1-year follow-up.26,27 Follow-up evaluation for lateral or medial epicondylitis should be ensured.

de Quervain’s Tenosynovitis. The initial treatment of de Quervain’s tenosynovitis consists of immobilization with a thumb spica splint, antiinflammatory medications, and prompt referral. Corticosteroid injections have been shown to be an effective treatment of de Quervain’s disease, and failure to respond may be due to anatomic variation or poor technique. A meta-analysis assessing the efficacy of corticosteroid injections revealed a number needed to treat (NNT) of two to obtain a beneficial outcome.28 Surgical decompression of the first dorsal compartment may be indicated if these treatments fail.

Achilles Tendinopathy and Rupture. In addition to routine conservative treatment, patients with Achilles tendinopathy should be referred for orthopedic evaluation and correction of limb malalignment with the use of orthotics or heel lifts. Eccentric loading exercises (Fig. 107.4) and low-energy shock wave therapy are effective therapies for Achilles tendinopathy. The management of Achilles tendon rupture may be either operative or nonoperative, depending on the patient involved. Appropriate consultation with an orthopedist is essential. A conservative approach, including immobilization in a walking boot with heel lifts and a specific, graduated rehabilitation program may be indicated.29 Some authors note that complete ruptures in active athletes should be treated surgically in most cases. Although other risks and benefits should be taken into consideration, some studies indicate that early surgery may be indicated because the risk for Achilles tendon rerupture is less.

Disposition

Most patients with tendinopathy are safely discharged home with proper discharge instructions, relative rest of the tendon, analgesia, and appropriate follow-up. The exceptions are elders and disabled patients who are often rendered unable to perform activities of daily living due to the tendinopathy. Although appropriate rest and analgesia provide symptomatic relief, underlying causes should be sought and modified.

Bursitis

Principles

A bursa is a closed sac lined by synovial membrane, which occurs in areas of friction between two layers of tissue. It permits fluid movement of soft tissue over areas of potential impingement (eg, subacromial bursa) or friction (eg, olecranon and prepatellar...
bursae). There are more than 140 bursae throughout the body. They develop after birth, most likely as a result of frequent irritation from movement.29 The olecranon and prepatellar are the two most common identifiably inflamed bursae and, when inflamed, they are recognizable over the extensor surface of the elbow and knee, respectively.

Many cases of bursitis are idiopathic in etiology, but common causes of inflammation include infection (most often due to Staphylococcus aureus), trauma (which may predispose to infection), rheumatologic disorders (eg, gout, pseudogout, ankylosing spondylitis, and rheumatoid and psoriatic arthritis) and other systemic diseases.

**Clinical Features**

**Olecranon and Prepatellar Bursitis**

Less than half of patients who present with olecranon or prepatellar bursitis show signs of an infectious etiology.31 Distinguishing septic from nonseptic bursitis can be difficult when basing diagnosis on clinical information and diagnostic testing. Patients with septic bursitis generally present earlier in their clinical course and tend to have more pain, tenderness, erythema, and warmth compared to those with nonseptic bursitis. Trauma is a common risk factor in septic bursitis, preceding the condition in up to 70% of cases. Other predisposing factors include chronic illness (such as, diabetes mellitus or alcohol abuse), chronic skin conditions (such as, atopic dermatitis), and previous non-infectious inflammation of the bursae (such as, rheumatoid arthritis or gout). It is also more common in people whose occupation results in repetitive knee or elbow trauma.

The olecranon bursa, found on the extensor surface of the elbow, is the only bursa of the elbow joint and is easily traumatized, which results in inflammation, pain, and swelling. Infection can also occur from local trauma (eg, puncture wound or laceration) but may also be present in the absence of visible trauma. Hematogenous bacterial seeding is rare, most likely because of limited vascular supply to the bursal tissue.

On physical examination, localized swelling and fluctuance are usually present over the bursa. There may or may not be evidence of trauma. Tenderness and warmth are typical in most patients with septic bursitis. Erythema with overlying cellulitis is also common in septic bursitis, and approximately 40% of patients will also have a fever.30,32 Tenderness, erythema, and warmth can also be seen in patients with purely inflammatory causes of bursitis, but the frequency and severity of these findings are less, and patients with septic bursitis usually present earlier in their clinical course.

Passive range of motion should not produce much pain, with the exception of full flexion, at which point there may be discomfort as the inflamed bursa is compressed. Evidence of significantly diminished range of motion, generalized joint swelling, or other signs and symptoms of joint involvement (eg, joint pain, warmth, effusion) should raise concern for septic arthritis. Although the olecranon and prepatellar bursae generally do not communicate with the joint space, septic arthritis should be considered in the differential diagnosis, especially if trauma is involved and the integrity of the underlying joint is disrupted. Arthrocentesis to rule out septic arthritis should be considered in these cases.

**Subacromial Bursitis**

The subacromial bursa lies between the supraspinatus tendon and the acromion. Subacromial bursitis is thought to be nearly synonymous with supraspinatus tendinopathy and may be involved in the stages of rotator cuff impingement. Pain and tenderness, localized to the lateral aspect of the shoulder, in addition to signs of impingement may be noted on physical examination.33 Although it is uncommon, septic subacromial bursitis can occur.

**Trochanteric Bursitis**

The trochanteric bursa has both deep and superficial components. The deep bursa is located between the greater trochanter and the tensor fasciae latae; the superficial bursa is located between the greater trochanter and the skin. Trochanteric bursitis is more common in middle-aged women, who usually report acute or chronic pain over the bursal area, as well as the lateral thigh. Lying on the hip and walking may exacerbate the pain. It can also occur as a complication of rheumatoid arthritis. On examination, the pain of superficial bursitis may be reproduced by palpation and hip abduction, and the pain of deep trochanteric bursitis may be reproduced with hip abduction. The hip joint usually has normal examination findings. Septic trochanteric bursitis is rare but has been described.34

**Ischiogluteal Bursitis**

The ischiogluteal bursa is located adjacent to the ischial tuberosity and overlies the sciatic and posterior femoral cutaneous nerves. Inflammation, known as wheaver’s bottom, is described as pain over the center of the buttocks with radiation down the back of the leg. Sitting on a hard surface exacerbates the pain, and palpation over the ischial tuberosity causes discomfort.

**Iliopsoas Bursitis**

The iliopsoas bursa is the largest bursa around the hip. It lies between the iliopsoas tendon and the lesser trochanter. The pain of iliopsoas bursitis usually is manifested as anterior hip pain that can radiate down the medial thigh to the knee and is increased on hip extension.

**Pes Anserine Bursitis**

The anserine bursa lies deep to the three tendons (sartorius, gracilis, and semitendinosus) that form the pes anserinus (“foot of the goose”) and superficial to the medial collateral ligament. The patient with anserine bursitis usually complains of medial knee pain approximately 2 or 3 cm distal to the joint line. There is usually tenderness to palpation in this area and occasionally swelling. Diabetes mellitus and possibly obesity and osteoarthritis of the knee are risk factors for development of this condition.

**Diagnostic Testing**

When there are signs of acute inflammation, aspiration of the bursa is indicated to exclude the presence of infection or crystal-induced disease.31 If bursal aspiration is performed, it should be done with sterile technique. An 18- to 20-gauge needle can be used to perform this procedure. A lateral approach has been recommended to lower the risk of iatrogenic sinus track formation, although the relation between the two is unclear. A distal approach can also be used when the olecranon bursa is aspirated. In cases of septic bursitis, the aspirate usually appears purulent but can occasionally appear serosanguinous or straw-colored. In the case of nonseptic bursitis, the aspirate varies from bloody to straw-colored. The bursal aspirate should be sent for evaluation of white blood cell (WBC) count with differential, microscopy for crystals (if crystalline disease is suspected), Gram stain, appropriate cultures and sensitivities, and glucose level. A bursal fluid glucose-to-serum glucose ratio of less than 50% is almost exclusively seen in septic bursitis.30
Organisms found on either Gram stain or culture is diagnostic for septic bursitis. There are no definitive guidelines about using the WBC count to distinguish between septic and nonseptic bursitis. A bursal fluid WBC count higher than 1000/µL is almost always seen, and one higher than 5000/µL suggests bursal fluid infection, even in the presence of a negative Gram stain. However, counts can be much lower in septic bursitis and above this level in nonseptic cases. Culture is the definitive test but will not be available during the initial evaluation. S. aureus is by far the most common organism in bursal infection, followed by other staphylococcal and streptococcal species, and this bacteriology has not changed in the last several decades. Because most cases of septic bursitis occur in the olecranon and prepatellar bursae, the diagnosis is made clinically in conjunction with aspiration. MRI can be used to aid in the diagnosis of inflammation or infection of deep bursae. Ultrasonography has also been used as a modality for aspiration of deep bursae.

Differential Diagnosis

Conditions that mimic bursitis include underlying fracture and osteomyelitis. Radiography and bone scan or MRI may be necessary to exclude these conditions. See Box 107.2 for details on the differential diagnosis for atraumatic, nonseptic bursitis.

Management

Septic Bursitis

The optimal treatment of septic bursitis is uncertain because large-scale clinical prospective trials in this area are lacking. Debate remains about the use of outpatient (oral) versus inpatient (intravenous [IV]) administration of antibiotics, duration of therapy, use of needle aspiration and incision and drainage, and use of operative intervention.

Patients who have bursal inflammation with suspicion (clinical or laboratory) of infection should be treated with appropriate antibiotics. Empirical therapy (including coverage for S. aureus and Streptococcus species) is indicated until definitive culture results are available. The frequency of methicillin-resistant Staphylococcus aureus (MRSA) in septic bursitis is unclear, although recent literature suggests that rates are low. MRSA was found to be the most common cause of community-onset adult septic arthritis in one case series from an ED population, so empirical coverage for this organism in septic bursitis should be considered. A trial of oral antibiotic therapy (up to 14 days) and treatment on an outpatient basis in the patient with uncomplicated septic bursitis and no underlying disease is reasonable. We recommend dicloxacillin (500 mg orally four times daily) or clindamycin (300 mg four times a day) for penicillin-allergic patients as first-line therapy. However, failure rates up to 67% have been reported for outpatient treatment of septic bursitis. One of the largest observational studies on the successful outpatient treatment of septic bursitis showed an admission rate of only 1 of 118 patients, but all patients in this study received sequential IV antibiotics for approximately 4 days at an outpatient clinic followed by a course of oral antibiotic therapy. Treatment in an observation unit or inpatient setting with IV antibiotics, therefore, is a consideration for patients with significant symptoms, overlying cellulitis, or those unlikely to receive close follow-up. For such patients, we recommend vancomycin (15 to 20 mg/kg/dose every 8 to 12 hours, not to exceed 2 g per dose) as initial empirical treatment.

Needle aspiration is a technique commonly used for the management of septic bursae. Successful treatment of septic bursitis can be achieved in patients receiving outpatient oral antibiotics after initial needle aspiration. One study showed no difference between patients who received aspiration and those who did not, but patients who had more severe disease were also more likely to be selected for drainage. These patients were also initially treated with parenteral antibiotics. Furthermore, the diagnosis of septic bursitis was confirmed by culture in only 26% of these patients, potentially underestimating the importance of bursal drainage in patients with true septic bursitis. Because needle aspiration is used for the diagnosis of septic bursitis, initial drainage at the same time seems warranted. Those with a purulent aspirate may require repeated aspiration at 1- to 3-day intervals if the effusion persists. In all cases, appropriate follow-up to assess response to therapy should be arranged. Warm soaks and wound care are also indicated. Surgical incision and drainage or bursectomy may also be necessary in severe, recurrent, or refractory cases.

Nonseptic Bursitis

Most cases of nonseptic bursitis improve with conservative therapy, although complete recovery can take many months. Initial treatment typically consists of aspiration of the bursa, which can relieve pain and increase range of motion, NSAIDs, and compression to prevent recurrent fluid accumulation. Systemic causes of bursitis (eg, crystalline disease) should be treated as indicated. Avoidance of local trauma is important for treatment and successful prevention of bursitis. Recurrent olecranon bursitis may be caused by underlying anatomic disorders, such as bone spurs.

Bursal injection with a combination of local anesthetics and steroids at the time of diagnostic aspiration is often therapeutically beneficial for inflammatory bursitis of deeper areas, such as the sub-acromial, pes anserine medial collateral ligament, and trochanteric bursae. Injections into superficial bursae has been used as a treatment modality, but multiple complications have been described, including skin atrophy over the bursa, persistent pain, development of septic bursitis, bleeding, post-injection flare as a result of release of microcrystals, and tendon rupture. However, a recent systematic review of treatment for olecranon bursitis found that patients who received a corticosteroid injection were no more likely to develop an infection or persistent pain than those who did not. At this point in time, we recommend non-injection treatment initially for suspected inflammatory bursitis of superficial bursae.

Disposition

Patients without underlying medical problems who present with uncomplicated septic bursitis can usually be discharged with appropriate oral antibiotics. Those with underlying diseases (eg, immunocompromise, leukopenia, and diabetes) and those with

BOX 107.2

Differential Diagnosis for Atraumatic, Nonseptic Bursitis

- Rheumatoid arthritis
- Pseudogout
- Ankylosing spondylitis
- Hypertrophic pulmonary osteoarthropathy
- Gout
- Scleroderma
- Systemic lupus erythematosus
- Whipple’s disease
- Idiopathic hypereosinophilic syndrome
systemic toxicity or severe bursal infection (e.g., purulent drainage) are candidates for IV antibiotics and inpatient therapy. Patients with a purulent aspirate or persistent infection may need repeated aspiration. Close follow-up is necessary to ensure response to therapy. Patients with presumed nonseptic bursitis require close follow-up as well.

**KEY CONCEPTS**

**Tendinopathy**
- Mechanical overload and repetitive microtrauma are key underlying mechanisms in the development of tendinopathy. Patients most often present with a history of progressively worsening localized pain after work- or sports-related activities that are repetitive in nature.
- Tendinopathy may also be associated with non-mechanical causes, including systemic manifestations of diseases, infectious etiologies, and the use of fluoroquinolones.
- Most patients with tendinopathy can initially be treated with conservative measures, such as protection, relative rest, application of ice, medications, and elevation. Overuse syndromes can take at least 6 to 12 weeks to heal. Inform patients of this, and provide an appropriate referral for follow-up.
- Emergent imaging is rarely indicated in the ED, although the use of bedside ultrasound to evaluate tendinopathy can help to identify tendon disruption/rupture.
- Operative treatment may be indicated for selected cases of tendon injury that require primary repair (e.g., rupture of the Achilles tendon) or that have failed to respond to conservative treatment (e.g., impingement syndrome) and are amenable to surgical amelioration.

**Bursitis**
- Consider the possibility of an infectious cause in all cases of acute bursitis.
- The definitive diagnosis of bursitis is made by aspiration of the bursa and evaluation of the fluid.
- Septic bursitis is most commonly caused by *Staphylococcus aureus*.
- Nonseptic bursitis may be traumatic, rheumatologic (e.g., gout and pseudogout), or idiopathic in nature. Other conditions, such as septic arthritis, osteomyelitis, and an underlying fracture, are in the differential diagnosis of bursitis.
- The management of bursitis includes treatment with appropriate medication (antibiotics for septic bursitis, NSAIDs for nonseptic bursitis), rest, application of ice, compression, and elevation, as well as prompt referral for appropriate follow-up. Hospitalization is considered for severe local infections, for patients who are immunosuppressed, and in the presence of high fever or systemic toxicity.

Answer: D. 

REFERENCES

CHAPTER 107: QUESTIONS & ANSWERS

107.1. Work-related injuries may be associated with which of the following?
A. Awkward working postures
B. Forceful exertions
C. Repetitive motions
D. All of the above

Answer: D. 

107.2. What is the etiology of most tendinopathies?
A. Direct blow to the tendon
B. Following complete tendon rupture
C. High-grade inflammation of the tendon
D. Mechanical overload and repetitive microtrauma

Answer: D. 

107.3. What is the causative organism in the majority of cases of septic bursitis?
A. Beta-hemolytic streptococci
B. Pseudomonas aeruginosa
C. Prototheca wickerhamii
D. Staphylococcus aureus

Answer: D. S. aureus is the most common cause of infectious bursitis.

107.4. What is the most important predisposing factor in septic bursitis?
A. Chronic obstructive pulmonary disease
B. Diabetes mellitus
C. Human immunodeficiency virus
D. Trauma

Answer: D. 

107.5. A 52-year-old male presents after feeling a “pop,” followed by pain to the back of his leg while playing basketball. You note a defect to his Achilles tendon and a positive Thompson’s test on examination. What should be the next step in the patient’s management?
A. Obtain an ultrasound in the emergency department (ED).
B. Obtain a magnetic resonance imaging (MRI) scan in the ED.
C. Perform a steroid injection to the affected tendon.
D. Split the affected leg in an equinus position and refer for prompt follow-up with orthopedics.

Answer: D. 

Although ultrasound and MRI can be important adjuncts to the diagnosis of a tendon injury, obtaining these tests...
from the ED is not necessary when the clinical diagnosis is obvious. Treatment consists of splinting the leg and close follow-up for either operative or nonoperative treatment.

107.6. A 42-year-old female with no significant past medical history presents with 4 days of edema, mild warmth, and mild erythema in the area of the right olecranon bursa. She is afebrile and has minimal tenderness to palpation of the bursa. You aspirate the bursa and obtain a whole blood count of 1500/µL. What should be the next step in the patient’s management?

A. Admit for intravenous (IV) antibiotics.
B. Apply a compression dressing and give ibuprofen.
C. Discharge the patient to home with oral antibiotics.
D. Obtain a magnetic resonance imaging (MRI) scan for further evaluation.

Answer: B. The clinical presentation and results of the fluid analysis highly suggest a nonseptic bursitis. Cases of nonseptic bursitis can be managed with a compression dressing, nonsteroidal antiinflammatory drugs (NSAIDs), avoidance of local trauma, and follow-up.
CHAPTER 108

Systemic Lupus Erythematosus and the Vasculitides

Robert T. Arntfield | Christopher M. Hicks

SYSTEMIC LUPUS ERYTHEMATOSUS

Principles

Background

Systemic lupus erythematosus (SLE) is a multisystem, autoimmune disorder that poses a challenge to the emergency clinician with its protean and occasionally dangerous manifestations. Morbidity for SLE patients is typically mediated through organ inflammation and destruction or the consequences of therapeutic immunosuppression. Further complicating lupus is the frequent association with the antiphospholipid syndrome (APS) and its corresponding venous and arterial thromboses. The diagnostic criteria reflective of its complexity and immunologic basis were first described in 1971. Today, the emergency department (ED) is a common venue for the evaluation and treatment of patients suffering from SLE.

Epidemiology

SLE is present in 20 to 70 per 100,000 of the general population. Although great variation in incidence exists worldwide, it is clear that two groups have consistently higher incidences: women, representing 90% of cases; and African Americans. Dramatic rises in incidence of SLE have been described during the past several decades, but it is suspected that this may be due to the implementation of more sensitive diagnostic criteria.

Etiology

The exact etiology of SLE is not understood. It is likely to be related to multiple factors; genetics, environmental factors, race, hormones, medications, and immunology have all been implicated to varying degrees.

With women representing 90% of SLE cases, a strong role for estrogen in disease development has been well supported in large cohort studies. The disease also has a strong genetic link, with high rates of monozygotic twin concordance and tremendous genetic overlap at the human leukocyte antigen (HLA) alleles.

Pathophysiology

SLE may cause disease in nearly any organ system in the body through inappropriate immune response to self and is often described as the prototype of all systemic, autoimmune disorders. Its exact pathophysiologic mechanism is not completely elucidated. When a cell cycle ends (apoptosis), intracellular contents, including DNA-rich nucleosomes, are released into the bloodstream. For patients with SLE, this cellular debris may be regarded as nonself (ie, an antigen) by the immune system. After exposure to these self antigens, the familiar immunologic cascade of antigen-presenting cells, T cells, and ultimately B cells and their plasma cell progeny is exacted, and patients form autoantibodies against their own cellular contents. These autoantibodies (which include anti-double-stranded DNA antibody, a commonly ordered rheumatologic assay in evaluation for SLE) may then mediate organ-specific disease and inflammation. This may occur through either direct attack and injury to parenchymal tissue or other mechanisms, such as formation of immune complexes that are deposited in tissue. On the basis of this immunologic understanding of the pathogenesis of SLE, the rationale for immunosuppression as both chronic and acute therapy for SLE can be appreciated.

The pathophysiologic mechanism of SLE may be different for each organ system. Indeed, the organ systems involved in any given patient’s disease may be different and may relate to the underlying presence or absence of antigens that resemble tissue from that organ system.

Clinical Features

In general, there are four broad presentations for a patient with SLE: (1) symptoms related to SLE that is not yet diagnosed (eg, idiopathic pericarditis, new rash), (2) progression or acute deterioration due to known SLE (eg, progressive nephritis, lupus enteritis), (3) complications of immunosuppression from treatment of SLE (eg, opportunistic infection), and (4) complaints or disease unrelated to SLE (eg, trauma, pregnancy).

The Patient With Undiagnosed or Suspected Systemic Lupus Erythematosus

Although some elements, such as the malar rash, that form the diagnosis of SLE are nearly pathognomonic for lupus, confidence in the initial diagnosis in the ED is difficult and probably rare. The literature is replete with ED-based case reports of extreme initial presentations with conditions such as Guillain-Barré, cardiac tamponade, and fulminant renal failure that subsequently were confirmed as complications of unrecognized SLE. However, in all cases the diagnosis of SLE was applied retrospectively. Because the evaluation for SLE is commonly conducted in a series of outpatient visits and relies on laboratory investigations that are uncommonly carried out in the ED, establishment of a new diagnosis of SLE in the ED is difficult. If a new diagnosis of SLE is suspected in an otherwise well patient, referral for an expedited evaluation is reasonable in most circumstances. The American College of Rheumatology classification criteria for SLE are presented in Table 108.1.

Acute Presentations in the Patient With Known Systemic Lupus Erythematosus

Emergency clinicians are commonly faced with evaluating the acute complaints of patients with an established diagnosis of SLE. The evaluation of SLE-related complications is based on use of a disease-specific differential diagnosis.
organ systems. Although such scoring systems have little role in the ED, it is important to identify when overall disease activity is increased because it typically signals the need to initiate or to escalate systemic therapy. In many cases, patients themselves are able to provide direction about the predictable course of their exacerbations and can be helpful in decision-making for therapy and disposition.

Specific Symptoms and Presentations of Systemic Lupus Erythematosus

Fever. Improving survival for patients with SLE during the past several decades has been achieved with the use of improved immunosuppressive regimens. As a result, patients with SLE are commonly affected by infections mediated by both typical and opportunistic organisms, suffering higher than average death rates from these infections. In one case series, infection was the leading reason for SLE patients to be admitted to the intensive care unit, superseding both renal failure and cardiovascular disease. Whereas absence of fever is insufficient in many cases to rule out infection, the presence of a fever is grounds for concern. Fever may also be due to increased overall disease activity. Given the heightened risk for SLE patients with infection, determination that a fever is due strictly to disease exacerbation should be made cautiously. Most infections in SLE are due to skin, lung, or urinary sources and are caused by typical organisms. However, largely because of the immunomodulating therapies that form the cornerstone of SLE management, opportunistic diseases are possible; *Pneumocystis (carinii) jiroveci* pneumonia, cryptococcal meningitis, *Listeria* infection, and herpes zoster have all been described.

 Neuropsychiatric Presentations. According to the American College of Rheumatology, there are 19 different clinical manifestations of neuropsychiatric SLE, some of which are included in the diagnostic criteria (see Table 108.1). These 19 different presentations vary widely and include seizures, confusion, cranial and peripheral neuropathies, demyelinating syndromes, myasthenia gravis, depression, psychosis, and anxiety. It may not be possible in the ED to determine whether such manifestations are due to neuropsychiatric SLE or to other, independent pathologic processes.

Headache. In general, headaches in a patient with SLE may be evaluated in a fashion similar to that for headaches in the general population. In one prospective cohort study, for instance, it was found that primary headache disorders, such as migraine and tension headaches, occur with the same frequency in SLE patients as in the general population. This was further supported by an extensive meta-analysis examining the implications of headache in SLE patients. In this study, the authors found no relationship between headache and SLE disease activity. Thus, despite recommendations to consider headache as suggestive of neuropsychiatric SLE or so-called lupus cerebritis, isolated headaches in the context of lupus may be treated in a fashion typical of other primary headache disorders. When a more malignant cause of headache is suspected, as suggested by meningismus, fever, or focal neurologic findings, an aggressive evaluation is warranted. When concern exists for an infectious cause of headache, consideration for opportunistic infections, such as cryptococcal meningitis, should be made in an immunosuppressed SLE patient. Further, because of common comorbid APS, consider sinus thrombosis in the SLE patient with new-onset focal central nervous system findings and headache.

Seizure. Because of incompletely understood mechanisms, seizures may occur as result of SLE disease activity. In one large series, seizures were observed in 11% of SLE patients, and in the majority of cases, either stroke or comorbid APS was present. Because of the high incidence of seizures, nonconvulsive status

APS, Antiphospholipid syndrome; CK-MB, creatine kinase MB fraction; CT, computed tomography; ED, emergency department; NSAIDs, nonsteroidal antiinflammatory drugs; SLE, systemic lupus erythematosus.

epilepticus is a consideration in SLE patients with an acute onset of altered mental status. The evaluation and management of seizures do not differ between patients with SLE and the general population.

**Focal Neurologic Findings.** On occasion, the patient with SLE may present with focal motor weakness. In those with SLE who also have APS, there is a significantly increased risk of stroke related to spontaneous arterial thrombosis. Demyelinating disease, such as Guillain-Barré and cranial neuropathies, have also been occasionally attributed to SLE from unclear mechanisms.

**Psychiatric Symptoms.** Mood disorders, psychosis, and anxiety are considered potential manifestations of neuropsychiatric SLE. Distinguishing SLE-related from functional causes of psychiatric presentations poses a challenge. Although psychiatric presentations of SLE in the ED have not been directly studied, in the absence of concern for an organic cause of altered mental status, patients with SLE are approached in the same manner as patients without SLE. Corroboration with the patient’s rheumatologist may provide insight to history of similar events or guidance for treatment.

**Cardiorespiratory Presentations and Diseases.** Chest pain, in the form of either pleuritis or pericarditis, is among the diagnostic criteria for SLE (see Table 108.1). In addition to pericarditis and pleuritis, coronary artery disease (CAD), pulmonary embolism, and musculoskeletal causes are also common. Other forms of cardiac disease that occur without chest pain, such as verrucous (Libman-Sacks) endocarditis and various arrhythmias, may also be present.

**Coronary Artery Disease.** There is a dramatically increased risk of CAD in the context of SLE. This was demonstrated in a compelling retrospective cohort study of 500 women with lupus compared with age-matched controls from the original Framingham data. In this study, a 52-fold increased risk of myocardial infarction was determined in women between 35 and 44 years old. These findings of increased risk of CAD have been supported by a number of other prospective trials. In one series, patients with SLE were found to be five times as likely to have CAD (based on coronary artery calcium scoring) as patients without SLE. In another series that profiled an even younger subset, it was found that among otherwise low- to moderate-risk women aged 22 to 45 years with complaints of chest pain, dyspnea, or decreased exercise capacity, there was an alarming 82% prevalence of CAD as determined by nuclear imaging. There was a similarly concerning prevalence of 43% of CAD in the asymptomatic “control” group who also had SLE. Further, traditional cardiac risk factors are found less often in patients with SLE who suffer consequences of CAD, suggesting that CAD in patients with SLE cannot be explained by the higher incidence of hypertension or hypercholesterolemia that these patients often exhibit. Thus, whereas there are many considerations for the cause of chest pain in patients with SLE (Table 108.2), CAD must be considered highly, and in fact more highly in patients who would otherwise be deemed to be low risk (young, reproductive age women). It is therefore appropriate to initiate an evaluation with electrocardiography, cardiac biomarkers, and stress testing to rule out acute coronary syndromes in patients with chest pain and SLE.

In addition to being at risk for development of CAD, patients with SLE who are treated with percutaneous coronary intervention appear to fare poorly. In one retrospective analysis of 28 patients with SLE receiving percutaneous coronary intervention, reintervention, death, and recurrent myocardial infarction were significantly more likely compared with a similar cohort without SLE.

**Pericardial Disease.** Pericardial effusion and pericarditis occur commonly in patients with SLE. It is estimated that symptomatic pericarditis occurs in 25% of patients with SLE during the course of their lives and that pericardial effusion occurs more often, frequently in a silent fashion, in up to 50%. In clinically evident SLE-related pericarditis, dyspnea or pleuritic chest pain is common. Typical electrocardiographic findings (Fig. 108.1) have been shown to be present in less than half of cases, however. Given the increased risk of CAD in patients with SLE, ST elevation of any kind found on an electrocardiogram warrants very careful consideration. When diagnostic uncertainty exists, echocardiography, cardiac enzymes, or cardiac catheterization may be complementary. Treatment of pericarditis includes nonsteroidal antiinflammatory drugs (NSAIDs) and glucocorticoids, as discussed later.

Pericardial tamponade, because of its dramatic nature, continues to receive attention as an initial presentation of SLE. However, large case series have shown that this life-threatening presentation occurs in less than 1% of patients with lupus. In large effusions without tamponade, medical management with high-dose glucocorticoids (1 to 2 mg/kg of methylprednisolone) has shown favorable outcomes in averting the need for pericardiocentesis.

**Pulmonary Embolism.** Pulmonary embolism and deep venous thrombosis occur with increased incidence in patients
Pneumonia. Pneumonia is the third most common infection in patients with lupus, after skin and urinary tract infections. Choice of antimicrobial coverage is determined by the severity of the infection and the degree of immunosuppression. For patients receiving long-term glucocorticoids or cyclophosphamide, coverage for organisms such as *Pseudomonas* and *Legionella* generally requires the use of a carbapenem or a fourth-generation cephalosporin in addition to either a respiratory fluoroquinolone or macrolide. There is no evidence to support the routine coverage for *P. jiroveci* in these patients.

Pleuritis. Pleuritis, due to autoantibodies acting against the pleura itself, is the most common respiratory condition occurring in SLE. Characterized by pleuritic chest pain with or without a pleural effusion or pleural rub, it has symptoms that overlap with those of other more serious conditions (see Table 108.2). If a pleural effusion is present, analysis of pleural fluid for antinuclear antibodies may be the most accurate method to confirm diagnosis but may be impractical in the ED. A diagnosis of pleuritis should be arrived at only after other causes of pleuritic chest pain in these thrombophilic, immunosuppressed patients have been ruled out.

Pneumonia. Pneumonia is the third most common infection in patients with lupus, after skin and urinary tract infections. Choice of antimicrobial coverage is determined by the severity of the infection and the degree of immunosuppression. For patients receiving long-term glucocorticoids or cyclophosphamide, coverage for organisms such as *Pseudomonas* and *Legionella* generally requires the use of a carbapenem or a fourth-generation cephalosporin in addition to either a respiratory fluoroquinolone or macrolide. There is no evidence to support the routine coverage for *P. jiroveci* in these patients.

Undifferentiated Dyspnea. Mitral valve insufficiency due to noninfectious vegetations, known as Libman-Sacks lesions, may cause a patient to experience dyspnea on exertion or, in rare severe cases, pulmonary edema (Fig. 108.2). Anemia, present in up to 50% of patients with SLE, may lead to a chief complaint of dyspnea. Both anemia of chronic disease and hemolytic anemia are common; hemolytic anemia is more typical in those also carrying aPL antibodies. In cases of severe anemia recognized in the ED, a Coombs test can be diagnostic for immunologic hemolytic anemia. Other less common but noteworthy causes of shortness
of breath in a patient with SLE include interstitial lung disease, lupus pneumonitis, diaphragmatic disease (so-called shrinking lung syndrome), and pulmonary hypertension.

**Musculoskeletal Presentations.** Musculoskeletal chest pain, related to underlying pectoral, intercostal muscle, or costochondral joint inflammation, may also occur in SLE. Similar to pleuritis, the threat of a more malicious underlying cause of pain should prompt the clinician first to seek other causes before arriving at this more benign cause. Treatment with NSAIDs or acetaminophen is generally appropriate.

Arthritis commonly afflicts those with SLE, and increasing severity of joint pain may be a marker of increasing disease activity or an SLE flare. Arthritis or arthralgias are typically symmetrical and nonerosive (unlike rheumatoid arthritis) and may involve multiple joints. Arthritis is most commonly present in the hands, wrists, and knees but may be manifested in any joint. Aside from mild tenderness, the joints are often normal on physical examination and rarely experience deformity. Uncommonly, septic arthritis may complicate SLE. In one large retrospective analysis of SLE-related hospitalizations, only 0.3% of admissions were for septic arthritis. Possibly because of immunosuppressant use, including corticosteroids, *Salmonella* is an unusually frequent culprit organism that was isolated in 59% of cases in one study and most commonly found in the hip. An isolated swollen joint is not typical of SLE and prompts consideration for infectious arthritis. If septic arthritis is suspected, diagnostic arthrocentesis is recommended. Empirical treatment with 1 gm of vancomycin and 1 gm of ceftriaxone will cover likely organisms, including *Salmonella*. Myalgias are common in SLE and may be an early marker of increasing disease activity for some patients. Generalized muscle pain is typical, but muscle weakness is uncharacteristic. If muscle weakness is present, an underlying myositis or myopathy secondary to steroid use is considered.

**Gastrointestinal Presentations.** The most common gastrointestinal manifestation of SLE is oral ulceration, which occurs in nearly a third of patients with SLE. Treatment includes local symptom management (chlorhexidine mouthwashes, viscous lidocaine) combined with systemic therapy (hydroxychloroquine) in more severe or refractory cases. Abdominal pain commonly complicates SLE. The causes of abdominal pain, with the exception of lupus enteritis, are largely similar to those in patients without SLE, such as pancreatitis, gastroenteritis, and peptic ulcer disease. Lupus enteritis (also known as mesenteric vasculitis) typically results in diffuse abdominal pain and is the most common cause of acute abdominal pain in SLE. The abdominal pain itself may also be associated with nausea, vomiting, and nonbloody diarrhea. Laboratory investigations, such as white blood cell count, hemoglobin level, platelet count, and erythrocyte sedimentation rate (ESR), are not helpful because they do not differ significantly between those with enteritis and those with abdominal pain due to other causes. Although no “gold standard” for the diagnosis of lupus enteritis has been established, computed tomography (CT) is the most useful test to assess for this condition. Several CT scan findings are supportive, including bowel wall thickening (Fig. 108.3), engorgement of mesenteric vessels, and increased attenuation of mesenteric fat.

When lupus enteritis is suspected, early pulse steroids, at a dose of 1 to 2 mg/kg of methylprednisolone per day, should be administered. Surgical consultation should be obtained in severe cases or when bowel necrosis has occurred. With aggressive medical therapy, which may also include cyclophosphamide, the need for surgical management is uncommon. Other, less common gastrointestinal illnesses to which SLE patients are predisposed include protein-losing enteropathy and intestinal pseudo-obstruction. Last, in assessing abdomen pain in patients with SLE, clinicians should be mindful of the effects of chronic steroid use and increased risk for both hollow viscus perforation and peptic ulcers, which may occur in the absence of traditional symptoms.

**Dermatologic Presentations.** The most characteristic cutaneous manifestation of SLE is the malar rash. The rash has a “butterfly” distribution of raised erythema over the bridge of the nose and malar eminences while sparing nose and nasal-labial folds (Fig. 108.4). The other most common skin lesion found in SLE is the discoid rash. Discoid lesions are circular and raised, scaly lesions that may be commonly found on the face, scalp, and ears, often in association with pigment change, alopecia, and severe scarring (Fig. 108.5). Cutaneous lupus may exist in isolation without systemic involvement. Mild cases of worsening cutaneous lupus are treated topically with 1% hydrocortisone cream. Moderate to severe cases are treated with topical calcineurin inhibitors or even systemic therapy (eg, hydroxychloroquine) in consultation with the patient’s internist or rheumatologist. In nearly all cases of SLE, avoidance of sun exposure is advisable and will help minimize cutaneous disease.

**Renal Disease.** Renal disease develops in approximately a third of SLE patients. Given a high prevalence and morbidity of renal disease as well as its tendency to carry few if any symptoms,
Nuclear imaging may be helpful to assess right ultrasound.

When a new diagnosis of SLE is being entertained, other more contributory in SLE patients taking glucocorticoids. It does, however, rise in the setting of infection and thus may be a useful laboratory marker to distinguish between a flare and infection. The ESR has less of a role because it has been shown to be elevated in SLE patients experiencing either a flare or an infection. Coagulation profile may show an elevated partial thromboplastin time (PTT) with a normal international normalized ratio (INR) in patients with SLE. This should raise concern for the presence of comorbid APS (see Special Considerations section).

**Imaging Studies**

**Radiography.** In SLE, a chest radiograph may point to diagnoses such as pleuritis (pleural effusion); pericardial disease (enlarged cardiac silhouette); pneumonia, including atypical and opportunistic infections (airspace disease); and pulmonary embolism (normal).

**Computed Tomography.** CT scanning may be of particular value in identifying lupus enteritis in the patient with abdominal pain, and CT pulmonary angiography has become the preferred imaging modality for pulmonary embolism. In both cases, attention to the presence or absence of lupus nephritis must be made to guide the appropriate and safe use of intravenous (IV) contrast material.

**Echocardiography and Ultrasound.** Bedside echocardiography may be carried out to evaluate the presence of pericardial fluid when pericarditis is suspected on the basis of clinical or electrocardiographic findings. A number of studies have documented the safety and accuracy of emergency clinicians identifying pericardial effusions with point-of-care ultrasound examination.

**Nuclear Imaging.** Nuclear imaging may be helpful to assess for pulmonary embolism in patients with chronic kidney disease due to lupus nephritis.

**Complications Due to Medications**

The remarkable improvements in life expectancy and disease control in SLE are costly. Chronic steroid use is associated with well-known consequences, such as increased risk of CAD, osteoporosis, avascular necrosis, psychosis, hyperglycemia, and weight gain, among many others. More potent chemotherapeutic medications, such as cyclophosphamide, methotrexate, and azathioprine, may profoundly influence the patient’s immune response and cause increased vulnerability to conventional and opportunistic infections. Chronic NSAID use for the musculoskeletal consequences of SLE may contribute to peptic ulcer disease, especially if they are coadministered with glucocorticoids. Therapy with antimalarials, such as hydroxychloroquine, is common and generally well tolerated; however, retinopathy and both QT interval prolongation and refractory ventricular arrhythmias have been associated with prolonged use.

**Diagnostic Testing**

Diagnostic tests will depend on the patient’s presentation and whether a diagnosis of SLE is already established or being suspected for the first time.

**Laboratory Tests**

In all but the most trivial presentations, order a serum creatinine concentration, urinalysis, and complete blood count because renal dysfunction, proteinuria, anemia, or thrombocytopenia may silently complicate SLE and be an important marker of increased disease activity. Leukocytosis, already a nonspecific finding, may be even less contributory in SLE patients taking glucocorticoids. When a new diagnosis of SLE is being entertained, other more specific immunologic assays, such as antinuclear antibody, anti-DNA, anti-Smith (Sm) antibody, and aPL antibody, can be ordered in the ED with the intent of outpatient follow-up for evaluation of results. Of note, antinuclear antibody is present in nearly all SLE patients but is also present in 50% of people who do not have SLE. Thus, the absence of antinuclear antibody virtually excludes the diagnosis. Unlike in other inflammatory disorders, C-reactive protein does not typically rise in response to increased disease activity in SLE. It does, however, rise in the setting of infection and thus may be a useful laboratory marker to distinguish between a flare and infection. The ESR has less of a role because it has been shown to be elevated in SLE patients experiencing either a flare or an infection. Coagulation profile may show an elevated partial thromboplastin time (PTT) with a normal international normalized ratio (INR) in patients with SLE. This should raise concern for the presence of comorbid APS (see Special Considerations section).

**Imaging Studies**

IV, Intravenous; PO, per os (by mouth).

Much of the pain and morbidity associated with SLE is related to inflammation that is amenable to treatment with NSAIDs. Ibuprofen 400 to 600 mg orally four times a day or naproxen 500 mg orally twice daily is useful for conditions such as pericarditis, pleuritis, arthralgias, myalgias, and fever. Use of NSAIDs in patients with chronic kidney disease due to lupus nephritis or a history of peptic ulcer disease is discouraged. In such patients, acetaminophen is used for mild to moderate pain, and narcotics are recommended for severe pain.

In cases of isolated cutaneous findings, topical treatment with corticosteroids is preferable to systemic therapy. Topical therapy may be initiated with 1% hydrocortisone cream to the affected area. In cases in which higher potency topical steroids are necessary, a preparation of 0.05% betamethasone applied once daily to the affected area for 2 weeks is appropriate.

**BOX 108.1**

Common Clinical Features of the Antiphospholipid Syndrome

Venous thrombosis
Arterial thrombosis (including stroke and transient ischemic attack)
Recurrent miscarriage
Livedo reticularis
Thrombocytopenia

**Special Considerations**

Antiphospholipid Syndrome

**Principles.** Present in nearly 40% of SLE patients, the APS is considered when patients both have a clinical history of thrombosis and are carriers of any one of a particular set of aPL antibodies directed against three specific serum proteins. These antibodies include the anticardiolipin antibody, the misleadingly named lupus anticoagulant, and the anti-β₂-glycoprotein I antibody. The most thrombogenic of the antibodies is the lupus anticoagulant, with an odds ratio as high as 16 for the development of venous thromboembolism and 10 for arterial thrombosis (stroke). In addition to being a strong risk factor for both venous and arterial thrombosis, the presence of APS in SLE has been shown to be an independent predictor of more severe disease and to be associated with increased intensive care unit mortality. Whether it is present in the context of SLE or independently, APS is an important cause of morbidity and mortality due to thrombosis.

**Clinical Features.** APS may present with any number of clinical features (Box 108.1), typically related to thrombosis or thromboembolism. A small subset of those with APS may present with multiple thrombotic sites and organ failures simultaneously. This condition is known as catastrophic APS.

**Diagnostic Testing.** Assays to detect and measure the presence of aPL antibodies are not generally available in a timely fashion and are impractical for use in the ED setting. However, there are two laboratory findings supportive of APS that may be useful or accidentally discovered during an ED evaluation:

1. A spuriously elevated PTT in the setting of a normal PT/INR may reflect APS. This in vitro finding, which contradicts the actual in vivo hypercoagulable state of the APS patient, is due to interference of the coagulation study by aPL antibodies. Confirmation of the presence of the interfering antibody is done by carrying out a mixing study. A mixing study requires repeating the PTT with a mixture of the patient’s blood and a 50% contribution from normal, control serum. In the presence of an inhibiting antibody, the PTT will remain elevated. If, however, the PTT was elevated for other reasons (most commonly heparin), the addition of normal clotting factors from the control serum will restore the PTT to normal.

2. The Venereal Disease Research Laboratory (VDRL) assay to test for syphilis contains cardiolipin and thus will commonly be falsely positive in patients with anticardiolipin antibodies or APS.

**Management.** For acute thrombotic events, anticoagulation with either unfractionated or low–molecular-weight heparin is generally indicated. After an initial thrombotic event, anticoagulation with vitamin K antagonists to maintain an INR between 2.0 and 3.0 is recommended. For patients with arterial thrombotic events (eg, stroke) or recurrent venous thromboembolic events, anticoagulation is recommended indefinitely. For patients

Reasons for Rheumatologic Referral for Patients With Systemic Lupus Erythematosus

- To confirm a diagnosis
- To assess disease activity and severity
- To provide general disease management
- To manage uncontrolled disease
- To manage organ involvement or life-threatening disease
- To manage or prevent treatment toxicities
- Special circumstances: Antiphospholipid syndrome (APS), pregnancy, surgery

Understanding the vasculitides as a heterogeneous group of disorders characterized by inflammatory damage of blood vessels. Arteries and veins suffering catastrophic APS, in addition to anticoagulation and glucocorticoids, intravenous immune globulin (IVIG), cyclophosphamide, and plasma exchange may all be indicated. Despite treatment, mortality for catastrophic APS approaches 50%.

Drug-Induced Lupus

Drug-induced lupus is an SLE-like self-resolving illness characterized by arthralgias, myalgias, rash, and serositis; it may be brought on by as many as 80 different medications. Notably, the malar rash and major organ involvement are rare in this condition. In drug-induced lupus, antibodies against the body’s own histone proteins are common and purported to be a major mechanism of disease. Although the list of potentially implicated medications is long, those agents with most evidence for causing drug-induced lupus are summarized in Box 108.2. The diagnosis is typically clinical and confirmed by resolution of symptoms with the withdrawal of the offending medication. In addition to cessation of the culprit drug, NSAIDs or steroids for symptom control are indicated.

Disposition

Disposition for the patient with SLE will vary significantly by clinical presentation. For patients with non–life-threatening presentations, such as increased musculoskeletal symptom burden, simple headache, or cutaneous reactions, discharge with appropriate follow-up is usually appropriate. However, patients with poor insight into their disease, significant comorbidities, or weak social or home supports may require hospitalization.

With disorders characteristic of SLE flares (eg, progressive lupus nephritis, lupus enteritis), new thrombotic events, and infectious complications due to immunosuppression, the patient may need admission for initiation of systemic therapy (eg, glucocorticoids, anticoagulation, antibiotics) and evaluation of response or deterioration. Admission to the intensive care unit is considered for those who, despite initial resuscitation, suffer progressive circulatory or respiratory derangement. Because of the high incidence of CAD in patients with SLE, patients with undifferentiated chest pain who have acute coronary syndrome ruled out in the ED should receive an expedited evaluation with provocative testing (eg, exercise stress test) in a chest pain unit, observation unit, or on an outpatient basis. If an outpatient evaluation is pursued, prescribe daily aspirin therapy. The complexity of SLE often challenges physicians not specialized in its many nuances and intricate pathophysiologic changes. Reasons for rheumatologic referral of patients with SLE are presented in Box 108.3.

Vasculitides

Principles

The vasculitides are a heterogeneous group of disorders characterized by inflammatory damage of blood vessels. Arteries and veins of all sizes and their tributaries can be affected to varying degrees. Presentations can range from benign and self-limited to serious and life-threatening. Diagnosis can be challenging because early vasculitis syndromes are nonspecific and can mimic other infectious, inflammatory, or neoplastic conditions. Approximately 1 in 2000 adults are affected by some form of vasculitis, with a higher incidence in adults 65 to 74 years old. In the United States, the most common vasculitis syndromes are giant cell arteritis (GCA), Wegener’s granulomatosis, and microscopic polyangiitis.

The cause of most vasculitis syndromes is unknown. Most cases are believed to result from immune complex deposition in blood vessel walls, prompting a complement-mediated inflammatory reaction. This results in vessel wall damage and necrosis, leading to stenosis, occlusion, and subsequent end-organ ischemia. The clinical manifestations are determined predominantly by the size and distribution of blood vessels involved along with the histologic subtype of inflammation.

The most recognized system for classification of the primary vasculitis is by the size of blood vessel involved (Table 108.5). Large-vessel vasculitis involves the aorta and its immediate branches and in some cases the corresponding vessels in the venous system. Medium-vessel disease involves the macrovascular lumen downstream from the main aortic branches. Small-vessel vasculitis involves capillaries, venules, arterioles, and glomeruli.

Clinical Features

Virtually all vasculitides involve some degree of constitutional symptoms, including fever, malaise, weight loss, and arthralgias. There is substantial overlap in the signs and symptoms associated with the large-, medium-, or small-vessel disorders. Practically, it is more useful to classify the vasculitides according to one of four patterns: (1) organ system involvement or exposure most evident on presentation vasculitis presenting with large-vessel occlusive symptoms, (2) vasculitis typified by pulmonary-renal manifestations, (3) vasculitis with characteristic cutaneous manifestations, and (4) syndromes associated with environmental or foreign antigen exposure. This approach assists in refining the differential diagnosis for a given constellation of symptoms and directing initial therapy while awaiting the results of confirmatory tests or tissue biopsy, which are in most cases not readily available in the ED.

Vasculitis Presenting With Large-Vessel Occlusive Symptoms

Giant Cell Arteritis

Principles. GCA, also known as temporal arteritis, is a systemic vasculitis that affects medium-sized and large vessels. The most recognized symptoms are caused by occlusion of the superficial
branches of the carotid artery. Although systemic medium- and large-vessel disease involving the carotid, subclavian, aortic, vertebral, and iliac vessels may also be present. The most feared complication of GCA is irreversible visual loss, occurring in up to one-third of patients. Early treatment can help prevent this complication, and thus the diagnosis is an important consideration in patients older than 50 years old presenting with any combination of constitutional symptoms, headache, visual changes, and jaw claudication.

**Clinical Features.** The incidence of GCA has increased steadily during the past 20 to 40 years. The syndrome is tightly coupled to age, with a mean age at onset of 70 years and a range of 50 to 90 years. The incidence increases sharply after the age of 50 years, with an estimated incidence of 33 per 100,000 patients. The disease is twice as common in women than in men, and smoking increases the risk of GCA sixfold in women.

GCA is frequently associated with a spectrum of nonspecific symptoms, such as fever, weight loss, and fatigue. Common presenting complaints include headache, visual symptoms, jaw claudication, and myalgias and associated polymyalgia rheumatica. Headache, the most common presenting symptom, occurs in three quarters of patients with GCA. Although it is classically located in the temporal area and in association with tenderness along the superficial temporal artery, no specific pattern of headache location or severity is predictive of the temporal arteries; and in untreated patients, the headache may improve or disappear, even though active disease is still present. The presence of tenderness, prominence, or beading of the superficial temporal artery on physical examination is associated with GCA, whereas the absence of any temporal artery abnormality is associated with a modest decrease in the likelihood of disease. Changes in visual acuity occur as a result of occlusive arteritis of the posterior ciliary artery or less commonly retinal artery occlusion. Visual loss may occur in one or both eyes and at times be painless; interruptions in acuity may be partial or complete, transient or permanent. The visual deficit is often profound, with 80% of patients unable to appreciate hand motion. Funduscopic findings in patients with acute visual loss include optic disk pallor and edema, in keeping with ischemic optic neuritis. Complete visual loss that is present for more than a few hours is usually irreversible. Diplopia may also occur as a result of ischemic ophthalmoplegia; oculomotor nerve lesions typically spare the pupil.

Thoracic aortic aneurysms are 17 times more likely to occur in patients with GCA compared with age-matched controls. The vertebral-basilar arteries are affected in 75% to 100% of patients, leading to signs of vertebrobasilar insufficiency, including gait disturbance, dizziness or vertigo, and vomiting. The diagnosis of GCA should be considered in elderly patients with signs of vertebrobasilar insufficiency in conjunction with constitutional symptoms and an elevated ESR.

**Diagnostic Testing.** In the presence of symptoms consistent with occlusion of superficial branches of the carotid artery, the diagnosis is usually straightforward. The American College of Rheumatology has developed a scoring system that lends equal weight to each of five diagnostic criteria (Box 108.4). Patients with a score of 2 or lower require temporal artery biopsy for the diagnosis to be confirmed; in patients with a score of 3 or higher, a biopsy adds little information beyond clinical and laboratory appraisal. An ESR of 80 mm/hr or higher is common, although approximately 20% of patients with an ESR of less than 50 mm/hr will go on to have biopsy-proven temporal arteritis. An elevated C-reactive protein level has improved sensitivity over ESR and may actually be the preferred diagnostic test, with a reported sensitivity for GCA of 97.5%. The gold standard for diagnosis remains temporal artery biopsy, with established sensitivity of 90% to 95%. Bilateral biopsies should be considered in patients for whom clinical suspicion is high and initial findings on biopsy are normal. The role of color duplex ultrasonography in the diagnosis of temporal arteritis remains controversial; one study showed no benefit in establishing the diagnosis when it was added to a carefully performed physical examination.
magnetic resonance imaging may be used alone or as a diagnostic adjunct to biopsy in atypical or challenging cases.

**Management.** Given the high stakes and morbidity associated with missed or delayed diagnosis, initiate treatment for temporal arteritis as soon as the diagnosis is considered to prevent permanent visual loss. The mainstay of treatment remains high-dose corticosteroids, initiated in the ED and continued until the diagnosis can be confirmed or excluded on subsequent biopsy. A typical initial regimen is oral prednisone 60 to 100 mg daily (or 1 mg/kg) with a temporal biopsy scheduled within 1 week of presentation. More than half of patients treated within 24 hours of presentation will achieve some recovery, compared with only 6% when treatment is delayed beyond this interval. Oral corticosteroids do not alter the sensitivity of temporal artery biopsy when it is performed within 2 weeks of initiation of therapy. Some authors recommend switching to IV corticosteroid treatment for 3 days should vision continue to deteriorate despite timely initiation of oral prednisone. Acetylsalicylic acid may be useful as an adjunct to decrease ischemic complications.

**Takayasu’s Arteritis**

**Principles.** Takayasu’s arteritis, also known as pulseless disease or occlusive thromboaortopathy, is a systemic large-vascular vasculitis of unknown etiology that primarily affects young women of Japanese and Southeast Asian descent. It is characterized by granulomatous inflammation of the aorta and its branches, leading to massive intramural fibrosis and symptoms of large-vascular stenosis, thrombosis, and aneurysm.

Takayasu’s arteritis is a rare disorder worldwide, with a reported incidence of 0.2 to 2.6 cases per million in Western Europe and North America, although this number is much higher in Japan. The disease is eight times more common in women than in men; symptoms are first manifested between 15 and 25 years old. The diagnosis should be considered in women younger than 40 years old who present with signs and symptoms of large-vascular occlusion, including upper limb claudication, decreased or asymmetrical pulses, and unexplained hypertension accompanied by constitutional symptoms, such as fever and weight loss.

**Clinical Features.** The most common presenting symptoms related to vascular occlusion are claudication (most commonly of the upper extremity, 35%), reduced or absent pulse (25%), hypertension (most often associated with renal artery stenosis, 20%), carotidynia (20%), lightheadedness (20%), and asymmetrical arm blood pressures (15%). Cerebrovascular ischemia, stroke, aortic insufficiency, and visual symptoms are present in 10% of patients. Approximately 80% of patients will have an identifiable bruit on physical examination, and 50% will go on to have asymmetrical blood pressures. One-third of patients will have cardiac complications, including aortic insufficiency and regurgitation, myocarditis, congestive heart failure, and cardiac ischemia from coronary artery aneurysm. Patients presenting after 40 years old or without signs of vascular occlusion pose a diagnostic challenge; only nonspecific constitutional symptoms or fever of unknown origin may initially be manifested, leading to diagnostic and therapeutic delays.

**Diagnostic Testing.** Although an elevated ESR (>80 mm/hr) is suggestive of Takayasu’s arteritis, the majority of laboratory investigations are nonspecific, and the diagnosis is almost always secured on the basis of clinical assessment and diagnostic imaging. Patients younger than 40 years old who present with symptoms of large-vascular occlusive disease (bruit, absent pulse, claudication) are candidates for axial imaging of the aorta and its major branches; options include CT angiography and magnetic resonance angiography, both of which have largely replaced digital subtraction angiography as the imaging method of choice.

**Management.** Once a diagnosis of Takayasu’s arteritis is made, oral corticosteroids (eg, 0.5 to 1 mg/kg prednisone daily) are indicated and continued for 4 to 12 weeks, followed by a gradual taper. It is a self-limited disorder in 20% of patients; the remainder will go on to have a relapsing-remitting or chronic progressive course requiring long-term corticosteroids. Steroid-sparing agents such as azathioprine, cyclophosphamide, and tumor necrosis factor inhibitors may be added for patients who relapse. Patients should be observed closely by a rheumatologist and vascular surgeon; those who do not respond to corticosteroids may benefit from surgical reperfusion, including bypass grafting and percutaneous transluminal angioplasty. Indications for admission include signs and symptoms of acute end-organ ischemia, aortic insufficiency, myocarditis, and decompensated congestive heart failure. The most common causes of death are congestive heart failure, renal failure, and infectious complications.

**Vasculitis Typified by Pulmonary-Renal Manifestations**

Vasculitis syndromes in this category are characterized by a predominance of pulmonary and renal manifestations, including dyspnea, cough, pulmonary infiltrates, and renal insufficiency secondary to glomerulonephritis, in addition to a variety of systemic symptoms. Wegener’s granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome share a strong association with the presence of antineutrophil cytoplasmic antibodies (ANCAs) of various subtypes, including cytoplasmic staining (c-ANCA) and perinuclear staining (p-ANCA), measured in the blood by enzyme-linked immunosorbent assay or direct immunofluorescence. Whether ANCA are involved in pathogenesis or are simply markers of disease is unclear. The absence of ANCA does not rule out an ANCA-associated vasculitis syndrome because between 20% and 50% will have negative assays.

A comparison of the common presenting features of Wegener’s granulomatosis, microscopic polyangiitis, Goodpasture’s syndrome, and Churg-Strauss syndrome is shown in Table 108.6.

**Wegener’s Granulomatosis**

**Principles.** Wegener’s granulomatosis is a c-ANCA–associated systemic necrotizing vasculitis of small and medium-sized blood vessels with a predilection for the upper and lower respiratory tracts and kidneys. The constellation of upper respiratory, pulmonary, and renal disease in patients with constitutional symptoms suggests Wegener’s granulomatosis. In the absence of pulmonary or renal symptoms, the diagnosis is extremely challenging and often missed. Wegener’s granulomatosis is more common in white individuals but otherwise shows no specific pattern of distribution for age, sex, or geography. The annual incidence is estimated to be 3 per 100,000 people.

**Clinical Features and Diagnostic Testing.** Constitutional symptoms including fever, malaise, and weight loss are often evident on initial presentation. Upper airway disease is the most common presenting symptom of Wegener’s granulomatosis, with 90% of patients developing upper respiratory tract symptoms in some form. Upper airway manifestations include serous otitis media with or without supplicative infection, hearing loss, sinusitis, nasal mucosal ulcerations and septal perforation, epistaxis, and laryngotracheal disease. Subglottic stenosis is the most common laryngotracheal lesion, present in about 16% of patients, with the common laryngotracheal lesion, present in about 16% of patients, with implications for airway management. Subglottic stenosis is the most common laryngotracheal lesion, present in about 16% of patients, with implications for airway management. Lower respiratory symptoms include cough, dyspnea, pleuritis, and hemoptysis. Radiographic studies may demonstrate pulmonary infiltrates and nodules, although the severity of radiographic findings does not always correlate well with symptom severity (Fig. 108.6). A minority of patients present with diffuse alveolar hemorrhage, which has an associated mortality of approximately
Combination therapy with corticosteroids and cyclophosphamide is considered the current standard of care for patients with acute flares and has dramatically changed the disease prognosis. Before the use of steroids, 1-year mortality approached 90%; combination therapy with corticosteroids and cyclophosphamide has improved the 5-year survival to nearly 90%, with the majority of patients achieving remission. Methotrexate plus corticosteroids may be used instead of cyclophosphamide in less severe presentations involving systemic disease. Patients presenting with new or suspected Wegener’s granulomatosis and those with severe disease require admission for high-dose IV dual-agent therapy. The diagnosis is typically confirmed by open lung biopsy. Patients who present with new respiratory symptoms or infiltrates on the chest film should be hospitalized and treated for infection, until it is proven otherwise, given the morbidity associated with pneumonia in an immunocompromised host.

*Antineutrophil cytoplasmic antibody (ANCA)-associated syndromes.
CSS, Churg-Strauss syndrome; ENT, ear, nose, and throat; WG, Wegener’s granulomatosis.

Fig. 108.6. A, Multiple intrapulmonary nodules on a chest radiograph of a patient with Wegener’s granulomatosis. B, Pulmonary nodules seen on computed tomography (CT) imaging. (From Adam A, Dixon AK: Grainger & Allison’s diagnostic radiology, ed 5, Philadelphia, 2008, Churchill Livingstone.)

50%. Renal dysfunction tends to be a later finding, developing in a subset of patients with generalized disease. Once progressive renal failure has developed, it may evolve rapidly during days to weeks, leading to end-stage renal disease that, if left untreated, is associated with a mean survival of 5 months. Chronic renal insufficiency can develop despite appropriate treatment, with a subset of patients requiring dialysis or renal transplantation. The list of associated symptoms in Wegener’s granulomatosis is myriad and speaks to the systemic nature of the disease. Ophthalmologic (scleritis, episcleritis, uveitis), cutaneous (palpable purpura, subcutaneous nodules, ulcers), neurologic (mononeuropathy and polyneuropathy, cerebral vasculitis, cerebral hemorrhage, or thrombosis), and cardiac (pericarditis, myocarditis) disease may be present to varied degrees.

**Management.** Initial management is directed at life-threatening pulmonary hemorrhage and sequelae from acute or decompensated chronic renal insufficiency. The combination of diffuse alveolar hemorrhage and subglottic stenosis represents a “double hit” difficult airway, requiring extreme caution during endotracheal intubation. Although a large endotracheal tube is preferred for the management of massive hemoptysis, selection of a smaller tube size may be required to bypass a narrow subglottic corridor. Fiberoptic intubation through an intubating laryngeal mask airway has been advocated.

Combination therapy with corticosteroids and cyclophosphamide is considered the current standard of care for patients with acute flares and has dramatically changed the disease prognosis. Before the use of steroids, 1-year mortality approached 90%; combination therapy with corticosteroids and cyclophosphamide has improved the 5-year survival to nearly 90%, with the majority of patients achieving remission. Methotrexate plus corticosteroids may be used instead of cyclophosphamide in less severe presentations involving systemic disease. Patients presenting with new or suspected Wegener’s granulomatosis and those with severe disease require admission for high-dose IV dual-agent therapy. The diagnosis is typically confirmed by open lung biopsy. Patients who present with new respiratory symptoms or infiltrates on the chest film should be hospitalized and treated for infection, until it is proven otherwise, given the morbidity associated with pneumonia in an immunocompromised host.
Goodpasture’s Syndrome

**Principles.** Goodpasture’s syndrome describes the clinical triad of glomerulonephritis, pulmonary hemorrhage, and circulating anti–glomerular basement membrane (GBM) antibodies. The syndrome is distinct from Goodpasture’s disease, which consists of glomerulonephritis and anti-GBM antibodies without pulmonary hemorrhage. Goodpasture’s syndrome is not associated with ANCA; anti-GBM autoantibodies target type IV collagen found in the basement membranes of glomeruli and pulmonary alveoli, causing autoimmune damage through a type II hypersensitivity reaction. The disease can affect people of all ages, with white individuals more commonly affected. The incidence is bimodal; one peak occurs in 20- to 30-year-old men and a second in 50- to 70-year-olds of both sexes. The incidence is believed to be about 1 case per 2 million individuals.

**Clinical Features and Diagnostic Testing.** There is substantial variation in the presentation of patients with anti-GBM disease. Pulmonary or renal symptoms may exist alone or in combination, although the two are most often present together. Fever, malaise, and weight loss are common early symptoms. Pulmonary symptoms range from dyspnea and cough to hypoxemia and frank pulmonary hemorrhage, which can be massive and life-threatening. Chest radiographic findings may be normal or demonstrate hilar pulmonary infiltrates sparing the apices and costophrenic angles. Renal failure can be insidious or be manifested as rapidly progressive glomerulonephritis with acute kidney injury and volume overload. Urinalysis shows characteristic signs of acute glomerulonephritis, including hematuria, proteinuria, and red cell casts. Definitive diagnosis is made by lung or renal biopsy demonstrating linear deposition of anti-GBM antibodies in the alveolar or GBMs, respectively.

**Management.** Initial management of patients with massive pulmonary hemorrhage is focused on securing a definitive airway and addressing hemodynamic instability. Bronchoscopy or chest radiography can be used to identify the source of hemorrhage, and selective intubation of the contralateral mainstem bronchus or use of a double-lumen endotracheal tube and ventilating with the affected lung in the dependent position may improve oxygenation.

High-dose methylprednisone (10 to 15 mg/kg) and cyclophosphamide are the mainstays of immune suppressive therapy. Therapeutic plasma exchange can be used to decrease the level of circulating anti-GBM antibodies during acute presentations. Patients who have end-stage renal disease may be candidates for renal transplantation, assuming anti-GBM antibodies are undetectable with treatment because the disease may recur in the transplanted graft. The prognosis has improved in recent years owing in part to the more aggressive use of therapeutic plasma exchange.

Microscopic Polyangiitis

**Principles.** Microscopic polyangiitis was first recognized in a subset of polyarteritis nodosa patients who presented with segmental glomerulonephritis. This systemic small-vessel vasculitis is the most common cause of the pulmonary-renal syndrome, leading to renal failure and pulmonary hemorrhage, the two most clinically relevant features of microscopic polyangiitis. The disease affects men and women equally and typically is manifested in the fourth or fifth decade of life, although it may occur at virtually any age. The annual incidence in the United States is approximately 3.8 cases per 1 million population.

**Clinical Features and Diagnostic Testing.** The characteristic presentation of rapidly progressive renal failure in the context of pulmonary alveolar hemorrhage and systemic symptoms occurs in the minority of patients; in many cases, the disease presentation is protean, consisting largely of renal insufficiency and constitutional symptoms, such as fever, weight loss, and malaise.

Glomerulonephritis with subsequent renal insufficiency is a nearly universal finding in microscopic polyangiitis, and renal failure can be acute and rapidly progressive or chronic and insidious; 25% to 45% of patients require dialysis at some point during the course of the disease. The specific renal disease is that of necrotizing glomerulonephritis, including elevated serum creatinine and blood urea nitrogen concentrations and a urinalysis demonstrating red cell casts, hematuria, and proteinuria. Pulmonary disease is present in up to 50% of patients, and diffuse alveolar hemorrhage is present in about 12%. Respiratory symptoms range from cough, dyspnea, and pulmonary fibrosis to massive diffuse alveolar hemorrhage requiring active and aggressive resuscitation and airway management. Peripheral neuropathy in the form of mononeuritis multiplex is present in up to 60% of cases. Skin manifestations are common, with about 50% of patients having palpable purpura.

It can be difficult to distinguish microscopic polyangiitis from other ANCA-positive syndromes, including Wegener’s granulomatosis and Churg-Strauss syndrome, on clinical grounds alone. Microscopic polyangiitis and Wegener’s granulomatosis probably exist on a spectrum of illness, and it is usually not required to distinguish between the two in the emergency setting to direct management. The diagnosis is typically secured by tissue biopsy of the lung, kidney, or skin, with demonstration of pulmonary capillaritis, necrotizing glomerulonephritis, or leukoclastic vasculitis, respectively.

**Management.** The priority in patients presenting with acute or decompensated chronic renal insufficiency is to identify and manage immediate life threats, including volume overload, electrolyte disturbances, and refractory acidosis. Airway management is the priority in those presenting with diffuse alveolar hemorrhage, and a difficult intubation should be anticipated. Admission for renal optimization, administration of IV steroids, and possibly dialysis is often required. In the presence of serious pulmonary and renal disease, a combination of high-dose glucocorticoid and cyclophosphamide is the treatment of choice, demonstrating superiority over glucocorticoid alone. Mortality in microscopic polyangiitis is approximately 30% during 7 years; morbidity and mortality are the highest in patients with a heavy burden of renal, cardiovascular, or neurologic disease. Plasmapheresis and IVIG are options for refractory cases. Remission is much more common than in Wegener’s granulomatosis and is achieved in about 90% of patients, although up to one-third will experience flares after remission.

Churg-Strauss Syndrome

**Principles.** Churg-Strauss syndrome, also known as allergic granulomatosis, is an autoimmune vasculitis of medium-sized and small vessels associated with asthma and eosinophilia. The etiology is unknown, although there is a strong association with allergy and atopy. The mean age at onset is typically in the fourth decade of life; men are affected more often than women are. The annual incidence is approximately 2.4 cases per 1 million individuals.

**Clinical Features and Diagnostic Testing.** Patients with Churg-Strauss syndrome may present in three distinct stages, although there may be considerable overlap and variance. Most patients with Churg-Strauss syndrome have asthma and allergic rhinitis several years before the onset of vasculitis. Over time, asthma symptoms may actually improve as the vasculitic stage of the disease sets in. The pattern of medium-sized vessels involved determines the clinical picture of the vasculitic phase, although pulmonary, renal, and neurologic symptoms are common. Pulmonary infiltrates, pleural effusion, and alveolar hemorrhage may be seen during the prodromal or vasculitic stage. Renal involvement is less common compared with other ANCA-positive vasculitides syndromes and may preferentially affect the lower urinary tract.
tract and prostate gland, leading to obstructive uropathy. Cardiac manifestations, including restrictive pericarditis and cardiomyopathy leading to congestive heart failure, are more common in Churg-Strauss syndrome compared with Wegener’s granulomatosis and microscopic polyangiitis. Mononeuritis multiplex, asymmetrical neuropathy, and cranial neuropathies are the most frequently observed neurologic symptoms, seen in up to 80% of patients. Gastrointestinal symptoms include infarction, perforation, and hemorrhage secondary to infiltration of the small bowel or stomach.

Laboratory investigation demonstrates a persistently elevated eosinophil count (>1500 cells/mm³), although this does not correlate well with the presence of active disease. Myeloperoxidase-ANCA antibodies are seen in about 40% of cases. Pulmonary infiltrates are typically patchy and transient in nature (Löfller’s syndrome). The diagnosis of Churg-Strauss syndrome is made by a combination of clinical and histologic features; evidence of necrotizing vasculitis or extravascular granulomas on skin or lung biopsy in conjunction with eosinophilia, asthma, and allergy is highly suggestive of the disease.

**Management.** Corticosteroids are the mainstay of treatment, although immunomodulating agents such as cyclophosphamide may be added to achieve remission in cases complicated by cardiac, renal, or gastrointestinal involvement. The overall survival for patients with Churg-Strauss syndrome approaches 80%, with an increased relative risk of death predicted by the presence of renal and gastrointestinal symptoms.

**Vasculitis With Characteristic Cutaneous Manifestations**

Cutaneous vasculitis involves inflammation of the blood vessels of the skin. The diseases listed here are associated with cutaneous manifestations that are often characteristic and an important element of disease recognition in the ED. Constitutional signs and symptoms of systemic multisystem disease may also be present.

**Erythema Nodosum**

**Principles.** Erythema nodosum, a vasculitis of the venules and veins of the skin, is characterized by tender, subcutaneous nodules on the tibial surfaces of the lower legs. Erythema nodosum is presumed to be a hypersensitivity response to systemic diseases or drug therapy, although no clear precipitant can be identified in 30% to 50% of cases. Peak incidence occurs in the spring or fall months among 18- to 34-year-olds, with a male-to-female ratio of approximately 1:4. The prodromal stage of erythema nodosum consists of nonspecific constitutional symptoms, fever, malaise, and myalgias. The distribution of subcutaneous nodules favors the lower extremities, although lesions may be appreciated on the forearm, trunk, and thigh (Fig. 108.7). The nodules tend to be erythematous, well circumscribed, and exquisitely tender to touch and develop a blue hue as they resolve. Arthralgias may be present in conjunction with or before the cutaneous eruption. Viral upper respiratory tract infections, streptococcal infection, tuberculosis, and sarcoidosis are common precipitants. Drugs associated with erythema nodosum include penicillins, sulfonamides, oral contraceptive medication, and phenytoin. Less common associations include autoimmune conditions, such as inflammatory bowel disease and SLE; histoplasmosis; *Yersinia, Salmonella,* and *Chlamydia* infections; coccidioidomycosis; and psittacosis.

**Management.** Management of erythema nodosum is generally supportive and directed toward symptom control and treatment or elimination of the underlying cause. Cutaneous nodules secondary to infection resolve within 6 to 7 weeks; in contrast, 30% of idiopathic cases may persist beyond 6 months. NSAIDs may be useful for control of arthralgias; corticosteroids and colchicine are reserved for the management of protracted or refractory disease.

**Henoch-Schönlein Purpura**

**Principles.** Henoch-Schönlein purpura is a small-vessel vasculitis characterized by palpable purpura and gastrointestinal and renal manifestations associated with immunoglobulin A immune complex deposition in blood vessels. The 1990 American College of Rheumatology criteria for Henoch-Schönlein purpura include the presence of two or more of the following: age at onset younger than 20 years old, palpable purpura, bowel angina, and vessel wall granulocytes on biopsy (sensitivity of 87.1%, specificity of 87.7%). Although the disease can affect adults, it is most commonly seen in children younger than 5 years old.

**Clinical Features and Diagnostic Testing.** Henoch-Schönlein purpura usually is manifested 1 to 2 weeks after a viral upper respiratory tract infection with a triad of palpable purpura, arthralgias, and abdominal pain. Purpuric lesions cluster in dependent regions with a predilection for the legs and buttocks (Fig. 108.8). Colicky abdominal pain and bloody stools can occur secondary to gastrointestinal vasculitis. A rare complication of Henoch-Schönlein purpura in children is enterointer Kelley intussusception (ileoileal, jejunojejunal, jejunoileal), which may be associated with severe abdominal pain, lethargy, bloody diarrhea, and signs of obstruction or perforation. Glomerulonephritis is typically mild and may be manifested as hematuria, red cell casts on urinalysis, and azotemia.

**Management.** Management in mild disease is generally supportive, and symptoms can intermittently recur for several weeks. NSAIDs control arthralgias in most cases but are avoided if renal impairment is present. Glomerulonephritis is treated more aggressively, with a combination of corticosteroids and cyclophosphamide, azathioprine, or mycophenolate mofetil, and generally demonstrates full resolution with time. Enterointer
Behçet’s Disease

Principles. Behçet’s disease is a complex, chronic small-vessel vasculitis that may affect the mucocutaneous, ocular, cardiovascular, renal, gastrointestinal, pulmonary, urologic, musculoskeletal, and central nervous systems. Early descriptions of the disease date to the time of Hippocrates and the third book of endemic diseases. The disease is defined by the presence of aphthous oral ulcers plus two or more of the following: genital aphthae; cutaneous lesions; and neurologic, oral, or rheumatologic manifestations. The exact pathogenesis remains unknown. Behçet’s disease is found worldwide, with the highest prevalence in Turkey, Japan, the Middle East, and Mediterranean regions. The disease affects people of all ages, although patients often first present in the second or third decade of life. The male-to-female ratio varies somewhat according to geography; women are more commonly affected than men in northern Europe and the United States, with an estimated prevalence in these regions of about 1 in 150,000 individuals.

Clinical Features and Diagnostic Testing. The triad of recurrent oral aphthous ulcers, genital ulcers, and uveitis in young adults is highly suggestive of Behçet’s disease. Oral aphthous ulcers are the defining characteristic of the disease (Fig. 108.9). The lesions are typically found on the tongue, lips, buccal mucosa, and gingiva; the tonsils, palate, and pharynx are less commonly affected. The ulcers are painful, have a yellow, necrotic base, and may appear alone or in crops of three to ten. Genital ulcers appear on the scrotum and penis in men and the vulva or vaginal mucosa in women. Skin lesions include erythema nodosum—like subcutaneous nodules, pyoderma gangrenosum, cutaneous thrombophlebitis, and pustular acne-like folliculitis. Ocular symptoms are common and constitute a major source of morbidity in Behçet’s disease. Findings may include uveitis, iritis, and optic neuritis. Hypopyon, once considered a characteristic feature of the disease, is uncommon. Visual symptoms may be bilateral or unilateral and trophes may require surgical intervention; prognosis in these cases is poor. Polyarteritis nodosa is almost always fatal if it is left untreated, although the prognosis has been much improved with the use of systemic corticosteroids. In a prospective study, the presence of two or more prognostic factors (azotemia, proteinuria, cardiomyopathy, gastrointestinal involvement, or neurologic signs) predicted a 5-year mortality of 46%; if none was present, the 5-year mortality was 12%.
can occasionally lead to permanent vision loss. Neurologic manifestations include brainstem and corticospinal tract syndromes (neuro-Behçet’s), aseptic meningoencephalitis, increased intracranial pressure, and cerebral sinus thrombosis complicated by optic nerve ischemia and atrophy. Gastrointestinal ulcers can cause obstruction or ileocecal perforation. Inflammatory oligoarthritis of the ankles, knees, elbows, and wrists is present in 40% to 60% of patients.

The diagnosis of Behçet’s disease is made primarily on clinical grounds. The appearance of genital lesions can be ambiguous, and other causes of painful genital ulcers need to be ruled out.

**Management.** Oral and genital ulcerations are often managed successfully with a topical steroid. Management of severe mucocutaneous disease involves systemic corticosteroids (e.g., prednisone, 1 mg/kg), low-dose thalidomide, or methotrexate. Treatment of systemic disease may be accomplished with a corticosteroid alone or in combination with cyclophosphamide or azathioprine. Ocular manifestations, including uveitis, are usually managed with prednisone plus azathioprine and require a rapid referral to an ophthalmologist. The presence of cerebral venous sinus thrombosis is an indication for immediate heparinization. Behçet’s disease often has a complicated and protracted course, with morbidity related primarily to ophthalmologic complications. Death can occur from neurologic, cardiovascular, and gastrointestinal sequelae or from complications related to long-term immunosuppressive therapy.

**Vasculitis Associated With Environmental or Foreign Antigen Exposure**

**Vasculitis Caused by Cocaine Adulterated With Levamisole.** Levamisole is an immune-modulating agent that has been used to treat autoimmune disorders, various forms of cancer, and the nephrotic syndrome. The drug has been withdrawn from the drug market in the United States owing to the frequency and severity of side effects, including antibody-mediated agranulocytosis and autoimmune vasculitis. Since 2005, the incidence of cocaine cut with levamisole (added at the source of supply to add bulk and weight to the raw product) has been increasing, and some 70% of cocaine seized at United States borders contains levamisole to varying degrees. Levamisole is not detected by routine blood and urine toxicology testing, and specialized testing with gas chromatography or mass spectrometry is of limited clinical utility given the short half-life of the drug (5.6 hours); it is unlikely to be detected in the plasma or urine beyond 24 to 72 hours after the last exposure.

The rash associated with levamisole involves tender palpable purpuric plaques with a predilection for the cheeks, nose, and earlobes (Fig. 108.10). Treatment is typically supportive; spontaneous resolution occurs with discontinuation of the offending agent. The agranulocytosis associated with levamisole is transient and fully reversible within a week to 10 days after discontinuation of the offending agent. Patients may present with asymptomatic agranulocytosis detected on routine blood work or with fever, sepsis, or signs of overwhelming infection. Febrile patients are treated with broad-spectrum antibiotics and a septic evaluation directed at the likely source of infection, similar to febrile neutropenia associated with chemotherapy. Afebrile patients are also often admitted for investigation and observation until their neutrophil count recovers.

**Cryoglobulinemic Vasculitis.** Cryoglobulins are immunoglobulins that precipitate from serum at cold temperatures. Damage to small and medium-sized blood vessels occurs when cryoglobulins bind to circulating antigens and deposit in vessel walls, prompting a complement-mediated inflammatory reaction and cryoglobulinemic vasculitis.

Three types of cryoglobulinemic vasculitis syndromes have been identified. Type I is associated with Waldenström’s macroglobulinemia and multiple myeloma and produces a syndrome of hyperviscosity with symptoms of presyncope, altered mental status, and stroke. Types II and III are known as the mixed cryoglobulinemias and represent 80% of recognized cryoglobulinemic syndromes. There is a strong association between these subtypes and hepatitis C, Sjögren’s syndrome, and SLE. The mixed cryoglobulinemias are manifested with a triad of purpura, arthralgias, and myalgias along with glomerulonephropathy and vasculitic peripheral neuropathy. Purpuric lesions are typically multiple and confluent and appear preferentially in dependent areas and the lower extremities in particular. Renal failure is the most serious consequence of cryoglobulinemia and is present in 20% to 60% of patients.

The diagnosis is based on the presence of serum cryoglobulins accompanied by typical clinical features; the most salient elements of the differential diagnosis include SLE and Henoch-Schönlein purpura. Skin biopsy can be helpful in confirming the diagnosis. Management involves identification and treatment of associated diseases, such as hepatitis C and multiple myeloma. Low-dose corticosteroids are helpful when systemic symptoms are present but should be avoided while antiviral therapy is being initiated. Plasmapheresis may be useful in life-threatening cases related to cryoprecipitation or serum hyperviscosity.

Features associated with Buerger’s disease, serum sickness, and hypersensitivity vasculitis are outlined in Table 108.7.

## KEY CONCEPTS

### Systemic Lupus Erythematosus
- Systemic lupus erythematosus (SLE) may affect any organ system. Thus, a fundamental understanding of the disease is required to tailor the differential diagnosis and evaluation.
- A 50-fold increased risk of coronary artery disease (CAD) and up to a 30-fold increased risk of venous thromboembolism in patients with SLE prompt chest pain evaluations in the emergency department (ED), even in young women.
- An elevated C-reactive protein level is more closely linked to infection in SLE patients and is not reflective of SLE disease activity.
- An isolated elevated partial thromboplastin time (PTT) in a patient with SLE prompts consideration for antiphospholipid (aPL) antibody carrier state and, if there is a history of thrombosis, antiphospholipid syndrome (APS).
- Steroids are the mainstay for management of the majority of conditions that are associated with increased SLE disease activity, including musculoskeletal, cutaneous, renal, pleural, and pericardial disease.

### Vasculitides
- Vasculitis syndromes should be considered in the presence of systemic symptoms, such as fever, malaise, and weight loss plus pulmonary, renal, or cutaneous manifestations.
- Massive hemoptysis and acute renal failure can occur in Wegener’s granulomatosis, Goodpasture’s disease, microscopic polyangiitis, and Churg-Strauss syndrome. Tracheal stenosis may be present in Wegener’s granulomatosis, further complicating airway management.
- Many patients with established vasculitis are receiving high-dose or combination immune suppressive therapy, making them vulnerable to opportunistic infections and overwhelming sepsis.

CHAPTER 108: QUESTIONS & ANSWERS

108.1. Which of the following statements is true regarding tinea capitis?
A. It is markedly contagious.
B. It is not transmitted by household pets.
C. Prednisone is contraindicated for the treatment.
D. Topical treatment is effective.
E. Treatment generally lasts 2 to 4 weeks.

Answer: A. Tinea capitis is the dermatophytosis that is markedly contagious. Systemic treatment for 4 to 6 weeks is the minimum. It may be transmitted by pets. When a kerion develops, prednisone (along with the antifungal) should be used to decrease inflammation and scarring.

108.2. A 16-year-old male presents with complaints of a chronic recurrent pruritic rash. It has primarily presented in joint flexor areas and first began at approximately 2 years old. His only other past history is asthma and hay fever. Physical examination reveals bilateral antecubital and popliteal papulovesicular lichenification and hyperpigmentation. It is intensely pruritic. Which of the following statements is true?
A. Adult-onset disease is common.
B. Corticosteroids are contraindicated.
C. Increased immunoglobulin E (IgE) levels are expected.
D. More frequent exacerbations are expected in the summer.
E. Skin changes are confined to the flexor areas of involvement.

Answer: C. This patient meets almost all criteria for atopic dermatitis. Onset after 5 years old should raise the question of an alternative diagnosis. The mechanism is believed to be eosinophil, mast cell, and lymphocyte activation by T cell production of interleukin-4. Elevated IgE levels are expected. Diffuse skin dryness is another prominent finding. Exacerbations may be triggered by increased body heat or stress, but they are more common in winter. Corticosteroids are the treatment mainstay.

108.3. A 29-year-old inmate presents with recurrent skin abscesses. Previous cultures have documented methicillin-resistant *Staphylococcus aureus* (MRSA) as the causative agent. It is resistant to clindamycin and sulfonamides. Which of the following antibiotics should be used for this case?
A. Cephalexin
B. Ciprofloxacin
C. Erythromycin
D. Linezolid
E. Rifamycin

Answer: D. MRSA is typically resistant to cephalosporins, macrolides, and fluoroquinolones. Rifamycin is effective but should not be used as the sole agent due to rapid development of resistance.

108.4. A 23-year-old male presents with nonpurulent cellulitis of his left leg. There is no obvious abscess. He has no other medical problems. Which of the following should be the antibiotic of choice?
A. Amoxicillin-clavulanate
B. Ciprofloxacin
C. Clindamycin
D. Doxycycline
E. Trimethoprim-sulfamethoxazole

Answer: B. Ciprofloxacin is the antibiotic of choice. The lesions have a predilection for the knees and elbows. Skin changes are not tender.

108.5. What is the parenteral treatment of choice for severe invasive *S. aureus* infection?
A. Bactrim
B. Clindamycin
C. Rifamycin
D. Vancomycin
E. Vancomycin and another antistaphylococcal agent

Answer: E. The combination is likely more effective due to enhanced bactericidal potential. Clindamycin and rifamycin are not indicated as parenteral monotherapy.

108.6. Which of the following statements is true regarding gonococcal dermatitis?
A. It affects primarily men.
B. It occurs in 1% or 2% of patients with gonorrhea.
C. Gonococci can usually be cultured from the lesions.
D. The lesions have a predilection for the knees and elbows.
E. The skin lesions are not tender.

Answer: B. Women are affected primarily. The lesions have a predilection for distal joint skin. They begin as red or hemorrhagic papules that evolve into pustules or vesicles with a red base. They are tender and may be confused with meningococcemia. They may later have a gray necrotic or hemorrhagic center. Skin cultures are usually negative.
108.7. Which of the following statements is true regarding drug eruptions?

A. A given drug produces a consistent eruption in the same patient.

B. A late-appearing drug reaction would suggest thiazide use.

C. Drug reactions tend to appear within 24 hours of drug initiation.

D. The most common cause of drug reactions are nonsteroidal antiinflammatory drugs (NSAIDs) and sulfa-based drugs.

E. The most common eruptions are urticaria and rashes.

**Answer:** E. The most common drug eruptions are urticaria and morbilliform rashes. Drug eruptions tend to occur within a week of drug initiation with the exception of semisynthetic penicillins, which tend to occur later. Penicillin is the most common cause of drug reactions, and patients with eczema, atopy, or asthma are at increased risk. A given drug may give widely diverse presentations in different patients or in the same patient on different occasions.
CHAPTER 109

Allergy, Hypersensitivity, and Anaphylaxis

Aaron N. Barksdale | Robert L. Muelleman

ALLERGY

Principles

Background and Terminology
The human immune system is an assemblage of cellular and humoral components working together in a highly complex, coordinated, and elegant fashion to achieve the primary goal of protecting the human host (self) from harmful offenders (nonself). Exposure to offenders activates the various immune mechanisms to bring about immune responses aimed at neutralizing the dangerous nonself while preserving self. The immune system, however, can overreact to otherwise harmless nonself agents, producing inappropriate responses that are harmful to the host, thereby giving rise to allergy or allergic diseases. These hypersensitivity reactions are manifested in clinical symptoms ranging from mildly inconvenient to fatal. For practical purposes, the term allergy is used in this chapter to refer to mast cell–mediated hypersensitivity reactions. For most allergic diseases to occur, predisposing individuals need to be exposed to allergens through a sensitization process called sensitization. Substances that elicit an allergic reaction are referred to as allergens, and those that elicit an antibody response (activated by B- and T-cell receptors) are called antigens.

On this allergic continuum, there are several important allergic syndromes frequently encountered in the emergency department (ED). *Urticaria* is a common allergic reaction to foods, drugs, or physical stimuli and is clinically characterized by an erythematous, raised, and pruritic rash. *Angioedema* is another important syndrome, mediated by either an allergic (histaminergic) mechanism in response to exposure to foods, drugs, physical stimuli, or a nonallergic (non-histaminergic) mechanism (eg, hereditary angioedema [HAE], or angiotensin-converting enzyme [ACE] inhibitor). Angioedema is characterized by edema of the subcutaneous or submucosal tissues, which can cause airway compromise if the tongue or larynx is involved. 1

At the other extreme of this allergic continuum is anaphylaxis, a life-threatening systemic allergic reaction characterized by acute onset and multiorgan involvement. Mechanistically, anaphylaxis is a type I hypersensitivity reaction (allergic), mediated by immunoglobulin E (IgE). In its most common form, anaphylaxis is precipitated by exposure to allergens in previously sensitized individuals (immunologic). 2 Previously, the term anaphylactoid reaction referred to a syndrome clinically similar to anaphylaxis that is not mediated by IgE (non-immunologic). Its clinical presentation and treatment are identical to that of anaphylaxis. Non-IgE (non-immunologic) reactions appear to result from direct degranulation of mast cells (and basophils) and may follow a single, first-time exposure to certain inciting agents. The current World Allergy Organization (WAO) guidelines use the term anaphylaxis to refer to both IgE- and non-IgE-mediated reactions, obviating the need for the term anaphylactoid reaction. 2

Pathophysiology

Because allergy is intimately related to immunology, a brief review is included in this chapter. Immunologic responses to antigens in humans are coordinated by two systems: the ancient innate immune system, which humans inherited from invertebrates; and the recently evolved adaptive immune system, which is present in humans and vertebrates (Fig. 109.1). The innate immune system is considered the first line of defense, characterized by its nonspecific but rapid responses to offending agents or microbes. Its effector components include resident cells (epithelial cells, mast cells, macrophages, dendritic cells, antimicrobial proteins), infiltrative cells (natural killer cells, neutrophils, monocytes, dendritic cells), and various proteins (antimicrobial peptides, complements, cytokines, pathogenic pattern recognition receptor [PRR] system). 3 The innate system responds to danger signals rapidly and nonspecifically, whereas the adaptive immune system takes time for antigen-specific cells (B and T cells) to amplify through a process known as clonal expansion, to mount a specific immune response. The T and B lymphocytes are capable of recognizing a myriad of antigens through a vast library of antibodies and receptors (up to 10^6). This diversity is accomplished by somatic rearrangement of fewer than 400 genes.

Development of the Immune System and Mechanism of Immune-Mediated Injury. The adaptive and innate immune systems originate from the common pluripotential hematopoietic stem cells, which are derived from the yolk sac and later reside in the bone marrow. These stem cells differentiate and develop into the lymphoid precursor cells and megakaryocyte (CFU-GEMM) stem cells. The lymphoid precursor cells differentiate into bursa-equivalent lymphocytes (B cells), thymus-derived lymphocytes (T cells), and natural killer cells. The CFU-GEMM cells develop into mast cells, basophils, and others (see Fig. 109.1). When the host encounters a foreign antigen, the cellular components of the adaptive immune system interact with the cellular and protein components of the innate immune system to mount a concerted defense aimed at neutralization of the antigen.

T-Cell Development. Lymphoid precursor cells migrate from the bone marrow into the thymus, where they continue their ontogeny. Under regulation by cytokines and cell-to-cell interactions, these precursors undergo gene rearrangement and positive and negative selection. In the process, T cells acquire the T-cell antigen receptors and various surface markers. Two types of T cells mature and come out of the thymus: CD4+, also called T helper cells (60% to 70%), and CD8−, also called suppressor T cells (30% to 40%). 4 Depending on the type of cytokine produced, T helper cells differentiate into type 1 helper (Th1) cells and type 2 helper (Th2) cells, with opposing activities. Th1 cells inhibit IgE production and IgE isotype switching, whereas Th2 cells stimulate IgE production and IgE isotype switching. The balance of these stimulatory and inhibitory activities of the Th1 and Th2 cells is believed to determine an individual’s propensity to develop...
allergic disease or atopy and may help explain the increased prevalence of allergy in urbanized and Western societies in the past three decades. Early in utero and soon after birth, naïve T lymphocytes in the infant’s immune system are dominated by the allergy-prone T<sub>H2</sub> cells and their associated cytokines (interleukins 4, 5, and 13). These cytokines are important inducers for production of IgE antibodies. Later, during infancy through early childhood and adolescence, the nonatopic infant’s immune system gradually shifts from this allergy-prone T<sub>H2</sub> environment to an allergy-protective T<sub>H1</sub> environment. The cytokines associated with this T<sub>H1</sub> environment include interleukin-2 and interferon-γ.

This shift is thought to be caused by the continual exposure of the young individual’s immune system to allergenic stimuli from the surrounding environment, mainly microbes. Features of Western lifestyles (such as, changes in infant diets, widespread use of antibiotics, smaller family size, and cleaner child care) are believed to reduce this stimulatory antigenic exposure in an individual’s early years, leading to an environment in which the immune system is dominated by a persistent allergy-prone T<sub>H2</sub> system (the hygiene hypothesis). This imbalance between the two immune systems is thought to be what ultimately leads to atopy and an allergy-prone population.

**B-Cell Development and Immunoglobulins.** B-cell ontogeny is divided into antigen-independent and antigen-dependent stages. During the antigen-independent stage, B cells mature in primary lymphoid organs (bone marrow and fetal liver), where they undergo gene rearrangement and acquire various surface markers. Later during the antigen-dependent stage in the secondary lymphoid organs (lymph nodes and spleen), B cells differentiate into memory B cells and plasma cells and are ready to secrete immunoglobulins. Throughout B-cell ontogeny, B-cell maturation, isotype switching, and immunoglobulin production are driven by activated T cells, cytokines, and interaction with antigen and bone marrow stromal cells.

Immunoglobulins are protein molecules composed of two identical polypeptide heavy chains and two identical polypeptide light chains, covalently linked by disulfide bonds (Fig. 109.2). The heavy (H) chains have one variable domain (V<sub>H</sub>) and three or four constant domains (C<sub>H</sub>). The light (L) chains have one variable domain (V<sub>L</sub>) and one constant domain (C<sub>L</sub>). The variable domains of the heavy and light chains together form a pair of identical antigen-binding sites and with the adjacent constant heavy domain pair make up the Fab (antibody-binding fragment) region of the immunoglobulin molecule. The remaining constant domains of the heavy chains together form the Fc (crystallizable fragment) region of the immunoglobulin molecule. The Fc binds to the surface receptors of effector cells, such as mast cells, B cells, or macrophages. There are five isotypes or classes of immunoglobulins (IgG, IgA, IgM, IgD, and IgE); isotype IgG has four subclasses (IgG1, IgG2, IgG3, and IgG4), and IgA has two subclasses (IgA1 and IgA2). The body usually produces IgM antibodies when it first encounters an antigen. Repeated antigenic exposure, however, may cause the constant region of the IgM to switch to another class (IgA, IgG, or IgE), a process known as *isotype switching.* Isotype IgE and IgG4 are the most important antibodies in the pathogenesis of allergic disease and anaphylaxis.

Mast cells, basophils, and their mediators are the central effectors in allergy and anaphylaxis. Exposure of a genetically predisposed individual to an allergen leads to the synthesis and release of allergen-specific IgE by plasma cells into the circulation. Fixation of this allergen-specific IgE to surface receptors on mast cells completes the process known as *sensitization.* These IgE-bearing mast cells usually reside in the mucosal surfaces, submucosal tissue (around venules), and cutaneous surfaces, where they are capable of becoming activated on reexposure to a specific allergen. Cross-linking of the mast cell receptors by a specific multivalent allergen sets off a cascade of conformational and biochemical
Anaphylaxis of mast cells with degranulation of mast cell mediators by antigen cross-linking of adjacent immunoglobulin E (IgE) on the cell surface. PAF, Platelet-activating factor.

**Classification of Reactions**

The term *allergy* is commonly used to describe clinical illnesses produced by excessive immune responses by a normal immune system to otherwise innocuous allergens. In this chapter, we adapt the classic Coombs and Gell classification to categorize these hypersensitivity reactions (Box 109.1).

Type I reactions (immediate hypersensitivity) are IgE mediated and account for most allergic and anaphylactic reactions observed in humans. Exposure to sensitizing allergens causes mediators from mast cells and basophils to be released through both IgE-dependent and IgE-independent (direct mast cell degranulation) mechanisms. Rhinitis caused by ragweed pollen and anaphylaxis caused by foods are examples of the IgE-dependent mechanism.

Type II reactions (cytotoxic) denote antibody-mediated cytotoxic reactions. Complement-fixing IgG (or IgM) engages cell-bound antigen, activating the classic complement pathway and leading to the fixation of membrane attack complexes on the cell surface and subsequent cell lysis. In the process, anaphylotoxins C3a and C5a cause mast cell mediators to be released, producing the same clinical syndrome seen in allergic anaphylaxis.

Type III reactions (immune complex) are IgG or IgM complex mediated. Circulating soluble antigen-antibody immune complexes migrate from the circulation to be deposited in the perivascular interstitial space, thereby activating the complement system. Anaphylactic reactions to blood transfusions and blood component therapy, including serotherapy (immunoglobulin administration), are examples of the overlap of type II and type III reactivity. They have therefore been classified as complement-mediated or immune complex–mediated anaphylaxis.

Type IV reactions (delayed hypersensitivity) are T-cell mediated and have no documented relationship to the pathogenesis of anaphylaxis.

**ANAPHYLAXIS**

**Principles**

**Epidemiology and Risk Factors**

The exact incidence of anaphylaxis is not known, but recent evidence suggests that it is increasing and that currently there are approximately 1500 fatal cases in the United States per year. In the last decade, experts in the field have developed specific consensus criteria to allow a more objective approach to diagnosing anaphylaxis. Recent literature suggests that over 50% of those patients presenting to EDs were misdiagnosed, and up to 80% did not receive appropriate first line treatment.

Pregnant women, infants, teenagers, and elders have been shown to have an increased incidence of anaphylaxis. Other risk factors include atopy (genetic predisposition to develop allergic disease), emotional stress, seasonal occurrence in summer to fall months, higher socioeconomic status, residing in northern locations (potentially correlating with vitamin D levels), and the presence of acute infection. Severe anaphylaxis has been associated
with poorly controlled asthma, history of mastocytosis, heavy physical exertion, exposure to a trigger during the concomitant use of certain medications (ACE inhibitors, beta-blockers, and nonsteroidal antiinflammatory drugs [NSAIDs]), and the history of a previous anaphylactic reaction (Box 109.2). In general, the more rapid an anaphylaxis reaction occurs after an exposure, the more likely it is to be severe and potentially fatal. The dose, frequency, duration, and route of administration of a drug can also affect the tendency to develop an anaphylactic reaction (eg, the parenteral route is more likely to lead to an anaphylactic reaction than the oral route). One interesting aspect of drug-related anaphylaxis is the constancy of administration. An anaphylactic reaction may not occur in an otherwise susceptible patient as long as a drug is administered at regular intervals. The same patient, however, may experience an anaphylactic reaction if the drug is resumed after an interruption of therapy.

ACE inhibitors can cause an accumulation of kinins and bradykinin and thus can exacerbate the angioedema component of anaphylaxis. Beta-blockers may oppose the actions of adrenergic agents used in anaphylaxis treatment. A recent study evaluating anaphylaxis in the ED demonstrated that the current use of any antihypertensive medication was associated with multi-organ involvement, more severe reaction, and increased incidence of hospitalization.7

Common Triggers for Anaphylaxis

Virtually any agent that is capable of activating mast cells or basophils can potentially precipitate an anaphylactic reaction. However, in up to 60% of adults and 10% of children, an inciting agent cannot be identified, and these reactions are classified as idiopathic anaphylaxis.1 When a trigger can be determined, foods, insect stings, and medications are the most common causes. Box 109.3 lists many of the common agents by their proposed immunologic mechanism.9

Foods. Foods are the major identifiable causative agents, accounting for approximately one-third of the cases of anaphylaxis. The most commonly identified foods are tree nuts, peanuts, fish, shellfish, soy, cow’s milk, and egg. The majority of the severe and fatal reactions appear to be associated with peanut and tree nut exposure, especially if the patient has a history of asthma.8 The majority of these reactions occur after ingestion but may occur after inhalation of food particles or even after skin contact with vomit containing the instigating agent. For a person with a known allergy, it may be difficult to avoid allergic reactions, because the allergen’s identity may be obscured during processing of the product (eg, consuming wine contaminated with Hymenoptera venom).

Insect Stings. Insect stings are the second most common cause of anaphylactic reactions, with the majority of them associated with hymenoptera venoms (wasps, bees, ants, and saw flies) and fire ant stings. These reactions typically require a sensitizing exposure, but there have been numerous reports of anaphylactic
BOX 109.3

Etiologic Agents Causing Anaphylaxis by Immunologic Mechanisms

**IMMUNOLOGIC MECHANISMS (IGE-DEPENDENT)**
- **Foods:** Egg, peanut, tree nut, milk, fruits, shellfish, soybean, sesame
- **Medications:** Antibiotics, NSAIDs, chemotherapeutic agents, immunomodulators
- **Insect stings:** Hymenoptera venoms, fire ant stings
- **Natural rubber latex**
- **Hormones:** Insulin, methylprednisolone, parathormone, estradiol, progestosterone, corticotropic
- **Local anesthetics:** Mostly ester family (procaine, tetracaine, benzocaine)
- **RCM**
- **Occupational allergens:** Enzymes, animal protein, plant protein
- **Aeroallergens:** Pollen, dust, spores, per dander

**IMMUNOLOGIC MECHANISMS (IGE INDEPENDENT)**
- **RCM**
- **NSAIDs**
- **Dextran**
- **Biologic agents:** Monoclonal antibodies, immunomodulators

**NONIMMUNOLOGIC MECHANISMS (DIRECT MAST CELL ACTIVATIONS)**
- **Physical factors:** Exercise, cold, heat, sunlight
- **Ethanol**
- **Medications:** Some opioids

**IDIOPATHIC (NO APPARENT TRIGGER)**

IgE, Immunoglobulin E; NSAID, nonsteroidal antiinflammatory drug; RCM, radiocontrast media.

reactions following first known stings or bites. Children tend to experience a more systemic cutaneous reaction, whereas adults are more likely to suffer hemodynamic collapse. Individuals displaying a large local reaction in the area of the sting or bite are less likely to suffer from a systemic reaction.24

**Drugs.** Antibiotics, chemotherapeutic agents, NSAIDs, and immunomodulators are the most common reported triggers, and drugs as a class represent the third most frequent cause of anaphylactic reactions.4

Penicillin is the most common drug-induced cause of anaphylaxis. Although patients often report a history of penicillin allergy, this may not stand up to close scrutiny. Studies have shown that up to 90% of individuals with a reported history of penicillin allergy can safely use penicillin. These individuals are usually mislabeled as penicillin allergic or lose their allergy after years of avoidance. Parenterally administered penicillin is responsible for the majority of these anaphylactic reactions.2,12

Cephalosporins share the β-lactam ring structure and side chains of the penicillins, but allergic cross-reactivity appears to be low, somewhere between 1% to 8% of patients. Patients who have experienced urticaria or anaphylactic reactions after taking penicillin are more likely to have an adverse reaction to cephalosporins, but even in this setting, the risk of an anaphylactic reaction is very low. In patients with a history of penicillin allergy, a cephalosporin is considered safe if they have had a negative penicillin skin test. If penicillin skin testing is positive, they could undergo a graded challenge or rapid desensitization process.12

Aspirin and other NSAIDs are believed to cause anaphylaxis through interruption of arachidonic acid metabolism, a non-IgE (non-immunologic) mediated process. The incidence of anaphylaxis to aspirin and NSAIDs varies widely, and these reactions appear to be drug specific and without cross-reactivity to other NSAIDs. Aspirin exacerbated respiratory distress (AERD) and NSAID-induced respiratory distress syndromes are unique in individuals with a history asthma or allergic rhinitis and are not considered anaphylactic reactions.12

Although corticosteroids are often used in the management of allergic syndromes and anaphylaxis, there have been reported anaphylactic reactions to these drugs. They appear to be rare, and the majority of them have been associated with the parenteral administration of methylprednisolone and hydrocortisone. When steroids are required in the management of other conditions, skin testing may demonstrate the specific agent responsible for the hypersensitivity, and allow for the substitution of a different class.12

**Natural Rubber Latex.** Natural rubber latex (NRL) allergy is the result of sensitivity to the proteins or chemicals contained in the latex products. This sensitivity reaction can be delayed (type IV) contact dermatitis or an immediate hypersensitivity (type I) reaction (see Box 109.1). In addition to rubber gloves, NRL can be found in an array of other hospital supplies, including endotracheal tubes, blood pressure cuffs, stethoscope tubing, airway masks, tourniquets, and catheters. NRL is also found in balloons, condoms, pacifiers, sports equipment, and toys. In recent years, most health care settings have incorporated the use of non-NRL gloves and products, making anaphylactic reactions from latex an uncommon event.24

**Radiocontrast Media.** Radiocontrast media (RCM) represents an important class of agents that can cause an anaphylactic reaction. Approximately 10 million radiologic studies using RCM are performed in the United States annually. Anaphylactic reactions to RCM are largely idiosyncratic, occur within minutes of infusion, and are independent of the dose. The pathophysiologic mechanism of anaphylactic reactions to RCM is unknown, but it is believed to be non-immunologic (non-IgE). Risk factors for an anaphylactic reaction include a previous adverse reaction to RCM, a history of atopy or allergic disease, asthma, and certain medications. A history of an allergy to fish or shellfish is not a contraindication to the use of the currently used RCM, nor does it increase the risk of an adverse reaction to RCM. Clinically, the risk for severe adverse reaction with ionic and nonionic contrast materials is less than 1%. The death rate from RCM reactions is estimated at 1 to 3 per 100,000 administrations of contrast material. Protocols have been developed to minimize risks of a serious allergic reaction in patients who have had a previous adverse reaction to RCM but who still require additional radiographic studies with contrast agents (Box 109.4).

BOX 109.4

A Standard Treatment Protocol for Patients With a History of Radiocontrast-Induced Anaphylaxis

Prednisone 50 mg by mouth given 13 hours, 7 hours, and 1 hour before the procedure
Diphenhydramine 50 mg PO given 1 hour before the procedure
Consider ephedrine 25 mg by mouth given 1 hour before the procedure
Consider an H1 antagonist, such as ranitidine 150 mg by mouth given 3 hours before the procedure
Exercise Induced Anaphylaxis. In certain settings, exercise has been recognized as an inciting event for an anaphylactic-like reaction. The mechanism is unclear, but the release of mediators from mast cells and basophils has been implicated. Patients with exercise-induced anaphylaxis are generally dedicated athletes who may have a personal or family history of atopy. In some individuals, anaphylaxis only occurs if specific co-triggers or cofactors are present during or prior to initiating exercise and typically do not cause symptoms without physical exertion. These may include certain foods, medications, or increased pollen levels in the area. Provocative foods, if identified, should be avoided. Patients should discontinue the exercise at the onset of rash or pruritus. When exercise is continued beyond this point, clinical deterioration is likely in susceptible individuals. Prophylactic treatment with an antihistamine may be helpful.2,13

Idiopathic Anaphylaxis. As previously mentioned, 30% to 60% of adults and up to 10% of children had no identifiable trigger for their anaphylactic reaction. The diagnosis of idiopathic anaphylaxis is often made after extensive evaluation by an allergist. In an attempt to prevent recurrent episodes, these patients are often treated with daily prophylactic medications, such as antihistamines and sometimes corticosteroids. Some women diagnosed with idiopathic anaphylaxis may actually represent “progesterone” anaphylaxis. Women suffering from this disorder experience recurrent episodes of anaphylaxis that are temporally related to their menstrual cycle.11

Mediators of Anaphylaxis

The numerous mediators released by mast cells and basophils exert overlapping physiologic effects on target organs and tissues, making it difficult to ascribe specific clinical manifestations to any one mediator. Histamine is the most important mediator and an essential contributor to immediate hypersensitivity and inflammation. Its infusion has been shown to produce the majority of the clinical features seen during an anaphylactic reaction (Table 109.1). There are three classes of histamine receptors: H1, H2, and H3. H1 receptor stimulation produces bronchial, intestinal, and uterine smooth muscle contraction. It also leads to increased vascular permeability, nasal mucus production, and eosinophil and neutrophil chemokinesis and chemotaxis. H2 receptor stimulation increases the heart rate, force of ventricular contraction, gastric acid secretion, airway mucus production, and vascular permeability, while also causing bronchodilation and inhibition of basophil histamine release. H3 receptors are found in neurons in the central nervous system and peripheral tissues, and they control the synthesis and release of histamine.14

In addition to histamine, there are several lipid metabolites produced through the prostanoid and leukotriene pathways that contribute to the adverse physiologic effects induced by histamine. Prostaglandin D2 (PGD2) is the main arachidonic acid metabolite released by activated mast cells. PGD2 and thromboxanes are synthesized from arachidonic acid through the cyclooxygenase pathway (through both COX-1 and COX-2). PGD2 induces hypotension, inhibition of platelet aggregation, and is approximately 30 times more potent than histamine in causing bronchoconstriction. The leukotrienes LTB4, LTC4, LTD4, and LTE4 are synthesized from arachidonic acid through the lipoxygenase pathway. They are involved in cholinergic-independent bronchoconstriction, increased vascular permeability, and increased mucous gland production.4 Platelet-activating factor (PAF) is a phospholipid and a potent compound that triggers human platelet aggregation. Its other actions include neutrophil activation and chemotaxis, along with ileal and parenchymal lung smooth muscle contraction. The clinical effects of PAF include decreased myocardial contractile force, coronary vasoconstriction, pulmonary edema, and prolonged increase in total pulmonary resistance with a decrease in dynamic compliance.14

Recent data has highlighted the important roles that nitric oxide and sphingosine 1-phosphate play in anaphylaxis. Sphingosine 1-phosphate can trigger calcium influx, stimulating synthesis of cytokines and mast cell degranulation. Nitric oxide is synthesized in vascular endothelium and its action can be increased by histamine, leukotriene, tumor necrosis factor alpha (TNF-α), and PAF. It is a potent vasodilator that contributes to the hypotension sometimes seen in anaphylaxis.14

Clinical Features

Anaphylactic reactions vary in duration and severity, but they are typically rapid in onset and may result in death. They often present as a combination of clinical characteristics, commonly affecting an array of organ systems including the skin (80% to 90% of episodes), respiratory tract (70% of episodes), gastrointestinal tract (30% to 45% of episodes), cardiovascular (10% to 45%), and the central nervous system (10% to 15% of episodes). Clinical presentations depend on the degree of an individual’s hypersensitivity; the quantity, route, and rate of antigen exposure; the pattern of mediator release; and the target organ sensitivity and responsiveness. Symptoms of anaphylaxis usually occur minutes after an exposure, although some reactions may develop hours after encountering the triggering agent. The National Institute of Allergy and Infectious Diseases/Food Allergy and Anaphylaxis Network (NIAID/FAAN) and WAO have adopted

TNF-α, Tumor necrosis factor alpha.
**Clinical Criteria for Diagnosis of Anaphylaxis**

Anaphylaxis is highly likely when any one of the following three criteria is fulfilled:

1. Sudden onset of an illness (minutes to several hours) with involvement of the skin, mucosal tissue, or both (e.g., generalized hives, itching or flushing, swollen lips-tongue-uvula) and at least one of the following:
   a. Respiratory compromise (e.g., shortness of breath, wheeze, cough stridor, hypoxemia)
   b. Reduced BP or associated symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
2. Two or more of the following occurring rapidly (minutes to several hours) after exposure to a likely allergen or other trigger for that patient:
   a. Involvement of the skin-mucosal tissue (e.g., generalized hives, itch-flush, swollen lips-tongue-uvula)
   b. Sudden respiratory compromise (e.g., shortness of breath, wheeze, cough, stridor, hypoxemia)
   c. Sudden reduced BP or symptoms of end-organ dysfunction (e.g., hypotonia [collapse], syncope, incontinence)
   d. Sudden gastrointestinal symptoms (e.g., crampy abdominal pain, vomiting)
3. Reduced BP after exposure to known allergen for that patient (minutes to several hours):
   a. Infants and children: Low systolic BP (age specific) or greater than 30% decrease in systolic BP
   b. Adults: Systolic BP of less than 90 mm Hg or greater than 30% decrease from that person’s baseline

*Low systolic blood pressure for children is defined as <70 mm Hg from 1 month to 1 year old, <70 mm Hg + (2 x age) from 1 to 10 years old, and <90 mm Hg from 11 to 17 years old.

BP: Blood pressure.

**Differential Diagnosis of Anaphylaxis**

- Acute generalized urticaria
- Asthma exacerbation
- Myocardial infarction
- Pulmonary embolus
- Syncope
- Adverse cutaneous drug reaction
- Anxiety/panic attacks

**FLUSH SYNDROME**

- Flushing associated with food
  - Alcohol
  - MSG
  - Sulfites
  - Scombroidosis
  - Carcinoid tumor
  - Peri-menopause
  - Thyrotoxicosis
  - Basophilic leukemia
  - Mastocytosis (systemic mastocytosis and urticaria pigmentosa)
- Vasointestinal peptide tumors

**SHOCK SYNDROMES**

- Septic shock
- Hypovolemic shock
- Cardiogenic shock
- Distributive shock

**MISCELLANEOUS**

- Hypoglycemia
- Acquired and HAE
- ACE inhibitor–associated angioedema
- Red man syndrome (Vancomycin)
- Neurologic disorders (seizure, stroke, autonomic epilepsy)
- Vocal cord dysfunction syndrome
- Pheochromocytoma

ACE, Angiotensin-converting enzyme; HAE, hereditary angioedema; MSG, monosodium glutamate.

Specific diagnostic guidelines to help clinicians increase and become more consistent in their recognition of anaphylaxis (Box 109.5). These diagnostic criteria have been validated in EDs and shown to be highly sensitive.16,17

The majority of anaphylactic reactions (80% to 90%) involve the skin. This may present as warmth and tingling of the face, mouth, palms, or soles, or as generalized flushing, pruritus, and diffuse urticaria. Nasal congestion, sneezing, ocular itching, and tearing are also common complaints. Patients presenting with angioedema may complain of swelling and a burning sensation in the affected area. This may be followed by mild to severe respiratory distress. The patient may present with a cough, a sense of chest tightness, dyspnea, or audible wheezes. Patients with laryngeal edema often complain of hoarseness, throat tightness, or stridor.49 Hypotension or dysrhythmias may be manifested as lightheadedness or syncope. Seizure activity due to decreased cerebral perfusion may be seen in rare instances. Gastrointestinal symptoms, more common in elders, include crampy abdominal pain and associated nausea, vomiting, diarrhea, or tenesmus.2,4 Anaphylactic reactions vary a great deal from one individual to another and even amongst different episodes in the same patient. It should be noted that hypotension and shock are rarely presenting features in infants and children and are much more common in the adult population.47 A summary of the observed clinical manifestations of anaphylaxis along with their related pathophysiologic changes is presented in Table 109.2.

**Differential Diagnosis**

The diagnosis of anaphylaxis is readily apparent in a patient presenting with acute rash, respiratory difficulty, and hypotension after an allergic exposure, but there are many other disease processes that may present with similar symptoms. Syncope, panic attacks, and asthma exacerbations are a few of the more common presentations to potentially instigate this diagnostic dilemma. Acute asthma exacerbation rarely presents with hypotension, abdominal pain, and a rash, but it could be very likely that a patient experiencing acute anaphylaxis has a history of asthma.4

Flush syndrome may occur from excess endogenous histamine release following certain ingestions, such as in scorbroidosis and in foods containing monosodium glutamate (MSG), but these isolated presentations will not display other clinical criteria required to meet the definition of anaphylaxis. Vasovagal syncope often presents with bradycardia, hypotension, and pallor, rather than the tachycardia, urticaria, and respiratory distress often associated with anaphylaxis.67 A list of differential diagnoses for anaphylaxis is found in Box 109.6.

ECG, Electrocardiographic.
Diagnostic Testing

Anaphylaxis is primarily a clinical diagnosis. A good history and physical examination are the best tools for making an accurate and efficient diagnosis of anaphylaxis. Box 109.3 lists the diagnostic criteria for anaphylaxis. Elevated serum histamine levels acquired within 1 hour and tryptase levels within 5 hours of the onset of symptoms have been shown to correlate with anaphylaxis. These laboratory tests are not helpful in the acute setting because the assays typically take over an hour to perform. Also, tryptase levels may not be elevated in food induced anaphylaxis.7,16 Screening studies should be aimed at ruling out other causes of anaphylactoid reactions. Failure to immediately provide these measures, even by a few minutes, could lead to hypoxia and even death.7

Management

Overview

In the setting of anaphylaxis, the key to avoiding adverse outcomes is prompt recognition and initiation of the appropriate interventions. Failure to immediately provide these measures, even by a few minutes, could lead to hypoxia and even death.7

Positioning

Hypotensive patients should be immediately placed in the supine position with their lower extremities elevated. If they are experiencing airway difficulties or vomiting, allow the patients to place themselves in a comfortable position with their lower extremities elevated. If they are experiencing airway difficulties or vomiting, allow the patients to place themselves in a comfortable position. After recognizing that anaphylaxis is present, a quick and initial effort should be made to remove any triggering agent (ie, insect stinger, stop infusion of medication). The patient’s breathing, circulation, skin, mental status, and body weight should be quickly assessed. The patient should be placed on a continuous cardiac monitor and pulse oximetry, have intravenous (IV) access established, and administered supplemental oxygen.7 The majority of the morbidity and mortality associated with anaphylaxis is caused by acute respiratory failure or cardiovascular collapse. Therefore, the next steps in management should focus on the triad of early administration of epinephrine, providing a patent airway, and expanding intravascular volume with IV fluids. Antihistamines (H₁ and H₂ blockers) and corticosteroids are commonly given in cases of anaphylaxis, but there is no objective evidence that they improve the overall outcome and should not be considered first-line medications.7,16

Box 109.7 summarizes the treatment algorithm in anaphylaxis.

<tbody>
<tr>
<td><strong>Treatment Algorithm for Anaphylaxis</strong></td>
</tr>
</tbody>
</table>

**EMERGENCY MEASURES (TAKEN SIMULTANEOUSLY)**
- Remove any triggering agent.
- Place patient in supine position.
- Begin cardiac monitoring, pulse oximetry, and blood pressure autonomic monitoring.
- Begin supplemental oxygen if indicated.
- Establish large-bore IV lines (eg, 16 or 18 gauge).
- Establish a patent airway.
- Be prepared for endotracheal intubation with or without rapid sequence intubation.
- Be prepared to use adjunct airway technique (eg, awake fiberoptic intubation, surgical airway).
- Start rapid infusion of isotonic crystalloid (normal saline):
  - Adults: 1000 mL IV in the first 5 minutes in the adult (several liters of normal saline may be required)
  - Pediatrics: 20 to 30 mL/kg IV increments

**ANAPHYLAXIS TREATMENT MEDICATIONS**

**First-Line Agent**
Epinephrine is the first-line medication and should be given immediately at the first suspicion of an anaphylactic reaction.
- Adult: 0.3 to 0.5 mg IM (1:1000 concentration) in anterolateral thigh every 5 to 10 minutes as necessary
- Pediatric: 0.01 mg/kg IM (1:1000 concentration) in anterolateral thigh every 5 to 10 minutes as necessary
- Alternatively, epinephrine (EpiPen, 0.3 mL; or EpiPen Jr, 0.15 mL) can be administered into anterolateral thigh

**Second-Line Agents (Should Not Precede the Administration of Epinephrine)**

**Antihistamines**
- Diphenhydramine:
  - Adults: 50 mg IV or 50 mg oral
  - Pediatric: 1 mg/kg IV or oral
- Ranitidine:
  - Adult: 50 mg IV (150 mg oral)
  - Pediatric: 1 mg/kg IV or oral
- Ipratropium:
  - Pediatric: 0.1 to 1.5 mg in 3 mL of normal saline; repeat as necessary
- Albuterol:
  - Pediatric: 0.25 mg, diluted to 3 mL of normal saline; repeat as necessary

**OTHER VASOPRESSORS TO CONSIDER**

Dopamine: 5 to 20 µg/kg per minute continuous IV infusion (titrated to desired effect)
Norepinephrine: 0.05 to 0.5 µg/kg per minute (titrated to desired effect)
Phenylephrine: 1 to 5 µg/kg per minute (titrated to desired effect)
Vasopressin: 0.01 to 0.4 units/min (titrated to desired effect)

**Aerosolized Beta-Agonists (if Bronchospasm Is Present)**
- Adults:
  - Albuterol: 2.5 mg, diluted to 3 mL of normal saline; may be given continuously
  - Ipratropium: 0.5 mg in 3 mL of normal saline; repeat as necessary
- Pediatric:
  - Albuterol: 2.5 mg, diluted to 3 mL of normal saline; may be given continuously
  - Ipratropium: 0.25 mg in 3 mL of normal saline; repeat as necessary

**Glucocorticoids (No Benefit in the Acute Management)**
- Methylprednisolone:
  - Adult: 125 to 250 mg IV
  - Pediatric: 1 to 2 mg/kg IV
- Prednisone/prednisolone:
  - Adult: 40 to 60 mg oral
  - Pediatric: 1 to 2 mg/kg oral

**REFRACTORY HYPOTENSION**
Consider continuous IV epinephrine drip (dilute 1 mg (1 mL:1000) in 1000 mL of normal saline or D₅W to yield a concentration of 1 µg/mL)
- Adults: 1 to 10 µg/minute IV (titrated to desired effect)
- Pediatrics: 0.1 to 1.5 µg/kg/minute IV (titrated to desired effect)

**PATIENTS RECEIVING BETA-BLOCKADE**
Glucagon: 1 to 5 mg IV over 5 minutes, followed by 5 to 15 µg/min continuous IV infusion

D₅W, 5% dextrose in water; IM, intramuscular; IV, intravenous.
themselves in a comfortable position and attempt to elevate their legs if possible. This positioning helps prevent distributive shock and allows epinephrine to reach the heart and be distributed throughout the body. Pregnant women should be placed in the left lateral decubitus position to prevent vena cava compression and to promote venous return of blood to the heart.

Epinephrine

Epinephrine should be the first medication given when a clinician suspects a patient is experiencing an anaphylactic reaction. The dose of aqueous epinephrine is 0.3 to 0.5 mg of 1:1000 concentration (1 mg/mL) intramuscularly (IM) for adults and 0.01 mg/kg of 1:1000 concentration IM for pediatric patients, and it can be repeated every 5 to 10 minutes as needed. It should be administered IM in the lateral, distal thigh (vastus lateralis). This has been shown to provide more rapid peak plasma concentrations (8 minutes) when compared to the previously suggested subcutaneous route (34 minutes).

If the patient remains hypotensive after multiple doses of IM epinephrine and adequate volume expansion aimed at increasing blood pressure, IV epinephrine should be considered. IV epinephrine increases the risks of cardiac dysrhythmias, thus requiring continuous cardiac and hemodynamic monitoring. Dilution and slow administration are recommended to reduce untoward effects. In adults, recent literature suggests preparing a concentration of 1.0 µg/mL and initially infusing at a rate of 1 µg/minute. The rate should be increased until hemodynamic stability is achieved or a maximum dose of 10 µg/min. This can be prepared by mixing 1 mg (1 mL) of 1:1000 concentration of epinephrine with 1000 mL of 5% dextrose in water or normal saline; this provides an infusion of 1 mL/minute equaling 1 µg/minute. In children and infants, an infusion rate of 0.1 µg/kg per minute is advised, increasing in increments of 0.1 µg/kg per minute to a maximum of 1.5 µg/kg per minute.

Central venous access is recommended when administering IV epinephrine because of the risk of tissue necrosis from extravasation. In addition to the IM route, successful administration of epinephrine through the intraosseous, sublingual, and endotracheal routes has been reported anecdotally, although only the parenteral route is recommended in recent guidelines. The dosage and concentration guidelines for these routes of administration of epinephrine are the same as those for IV administration.

Epinephrine derives its therapeutic value from its combined alpha-adrenergic and beta-adrenergic actions. Alpha-1-adrenergic stimulation increases vasoconstriction, increases peripheral vascular resistance, and decreases mucosal edema. Through beta-2-adrenergic stimulation, increases inotropic and chronotropic cardiac activity is enhanced. Beta-2-adrenergic stimulation also provides stabilization of mast cells and basophils, and it induces bronchodilation. These combined effects result in decreased mediator release from mast cells and basophils, which improves hives and bronchospasm, decreases mucosal edema and swelling, and reverses systemic hypotension. Epinephrine therefore works directly to improve the clinical features most commonly observed in an anaphylactic reaction.

Epinephrine can produce a number of undesirable side effects, including palpitations, anxiety, tremor, pallor, dizziness and headache. Ventricular arrhythmias, pulmonary edema, and hypertensive crisis are more severe adverse events that are known to occur, but they are often related to IV administration or toxic levels due to inappropriate dosing. Despite these concerns, the benefits of early administration of epinephrine in anaphylaxis far outweigh any of the stated risks. There are no absolute contraindications to the use of epinephrine, which is the drug of choice in anaphylaxis and anaphylactic shock.

Airway

Patients in respiratory distress and receiving multiple dose of epinephrine should be placed on supplemental oxygen and prepared for possible advanced airway management. Patients with bronchospasm may benefit from bronchodilators or nebulized beta-agonists, but this should not preclude the administration of epinephrine. Upper airway obstruction from laryngeal angioedema can progress rapidly, so preparations for a difficult airway should be made early. This may include an awake intubation with the assistance of fiberoptic laryngoscopy or the necessary equipment to provide a surgical airway.

Volume Expansion

Along with airway assessment, fluid resuscitation should be initiated. For adults, infuse 1 to 2 liters of normal saline rapidly through large-bore (eg, 16-gauge) IV lines. Pediatric patients should be given boluses in 20 mL/kg increments. When IV access cannot be established, intraosseous catheter placement is an alternative. The assistance of an infusion pump or pressure bag should be used when administering fluids in this manner. Large volumes of normal saline (2 to 7 liters) may be required to reverse the effects of fluid extravasation into the extravascular space and the circulatory collapse sometimes seen in anaphylaxis. Patients with heart failure or renal failure should be monitored closely for signs of volume overload.

Antihistamines

H1 and H2-antihistamines may be considered as adjunctive and second line treatments, but they should not replace the administration of epinephrine in the management of anaphylaxis. H1-antihistamines may help relieve cutaneous symptoms, such as urticaria, pruritus, angioedema, eye and nasal symptoms, and flushing. H2-antihistamines can contribute to relief of these cutaneous symptoms and are thought to be synergistic when given with H1-antihistamines. See Box 109.7 for suggested dosing.

Glucocorticoids

Glucocorticoids have no immediate role in the acute management of anaphylaxis and should be considered as third line interventions. Their onset of action typically does not occur for several hours, and they should not be administered before first and second line treatments. They may, however, provide benefit by preventing protracted symptoms or a biphasic reaction, but this has never been proven. Currently, there are no studies that have specifically evaluated the role of glucocorticoids in the treatment of anaphylaxis. See Box 109.7 for suggested dosing.

Patients Receiving Beta-Blockade

Glucagon, with positive inotropic and chronotropic cardiac effects mediated independently of alpha and beta receptors, may be helpful in patients with anaphylactic reactions who are receiving beta-blockers and who do not respond to epinephrine and other standard treatment modalities. The initial IV dose is 1 to 5 mg for adults and 20 to 30 µg/kg (maximum dose 1 mg) for children and may be followed by an infusion of 5 to 15 µg/minute. Nausea and vomiting are common side effects, so the clinician should be prepared to administer an antiemetic when indicated.

Disposition

Up to 20% of patients may experience a biphasic reaction defined as a reoccurrence of symptoms without reexposure to the
urticaria that last less than 6 weeks are considered acute (90%), and those persisting longer than 6 weeks are classified as chronic (10%). There are also several types of inducible urticaria including cold contact, delayed pressure, heat contact, solar, aquagenic, cholinergic, and contact urticaria.23-24

Angioedema is characterized by edema of the subcutaneous or submucosal tissues, commonly involving the face, mouth, lips, tongue, extremities, and genitalia. It is a result of abrupt vasodilation and increased vascular permeability, allowing fluid to move from the vascular to the interstitial space. Because the swelling is located in the deeper layers of the skin, the appearance is often normal in color and patients may complain more of a pain or pressure type sensation, rather than an itch. Of particular concern is when the tongue, posterior pharynx, or larynx is involved, which could progress to airway obstruction and compromise. Angioedema is mediated either by an allergic (histaminergic) mechanism in response to an exposure to foods, drugs or physical stimuli, or by a nonallergic (non-histaminergic) mechanism (eg, HAE or ACE inhibitor).23

Non-histaminergic (nonallergic) angioedema is typically a result of elevated bradykinin levels. This classification includes HAE with or without C1 esterase inhibitor deficiency, acquired C1 esterase inhibitor deficiency (ACID), ACE inhibitor–induced, and idiopathic angioedema. In the case of HAE with C1 inhibitor deficiency and ACID, the lack of C1 inhibitor causes activation of the kallikrein-kinin system, increasing the consumption of kininogen, resulting in increased production of bradykinin. In the setting of ACE inhibitor–induced angioedema, the inhibition of ACE, one of the main inactivators of bradykinin, results in increased bradykinin levels.23

Recent literature suggests that non-histaminergic angioedema is responsible for approximately 80,000 to 112,000 ED visits annually, and 30% are a result ACE inhibitor–induced angioedema. This has an overall incidence of 0.1% to 0.2%, but is three to four times more likely in African-Americans, and women are at a 50% higher risk than men. ACE inhibitor–induced angioedema has a predilection for the face, often involving the lips, eyelids, tongue, larynx, or pharynx. The highest incidence occurs in the first month of therapy but has been reported to occur as many as 10 years after therapy was initiated.23,25

Diagnostic Strategies

Similar to anaphylaxis, angioedema is a clinical diagnosis. There are no laboratory tests that are helpful in the acute setting. The majority of cases of acute urticaria and angioedema are hypersensitivity reactions, commonly triggered by allergens. A detailed history should focus on identifying any recent exposures to foods, drinks, physical stimuli, infection (especially viral hepatitis), occupational elements, or insect stings. Patients should also be questioned about prior history of similar symptoms and any family history of non-histaminergic angioedema.

Management

Angioedema With Urticaria

Angioedema that occurs in conjunction with urticaria is typically histaminergic (allergic) in nature. In cases that do not meet the criteria for anaphylaxis, antihistamines are considered the first-line treatment. Second-generation H1-antihistamines, such as cetirizine, loratadine, and fexofenadine, are the preferred agents, and up to fourfold the conventional dose may be considered. Because 15% of the histamine receptors in skin are H3, the addition of an H3-antihistamine (eg, ranitidine) may also be beneficial. A short course of oral corticosteroids (eg, prednisone) may be considered as a second-line therapy.23 In patients with
severe symptoms and no cardiac risk factors, epinephrine may be considered (anaphylactic dosing). In an effort to prevent recurrence, the patient should be educated to avoid exposure to potential agents that triggered their event.

**Angioedema Without Urticaria**

Acute attacks of non-histaminergic (bradykinin-related) angioedema do not typically respond to treatment with epinephrine, antihistamines, or steroids. In situations threatening respiratory compromise, paralytics should be given with caution, and the clinician must be prepared to use alternative measures to secure the patient’s airway (e.g., fiberoptic laryngoscopy, surgical airway).

Fresh frozen plasma (FFP), which contains C1 inhibitor, has been reported to be effective in abolishing acute attacks; however, there are rare reports of exacerbation of the angioedema by FFP. Several new agents are approved by the FDA for use in the United States in patients with known HAE. Berinert is human plasma derived C1-esterase inhibitor (C1-INH) concentrate and is approved for treatment of HAE in the United States. The dose is 20 units/kg IV. Ecallantide is kallikrein inhibitor that is administered as three separate 10 mg subcutaneous injections for a total of 30 mg. Icatibant is a bradykinin 2-receptor inhibitor that is administered as a single subcutaneous injection of 30 mg. Conestat alfa (Ruconest) is a recombinant C1-INH concentrate that is given IV at a dose of 50 units/kg.

**Disposition**

There is a lack of data to provide concrete guidelines for disposition. Most will agree that patients who experience a complete resolution of their angioedema, or have facial involvement only, can be discharged home after a period of observation in the ED. Hospitalization should be strongly considered for patients with persistent angioedema of the sublingual area, tongue, soft palate, pharynx, or larynx.

In patients presenting with airway threatening angioedema and no prior history, it is suggested to initially administer epinephrine and antihistamines at anaphylactic doses. As previously mentioned, non-histaminergic angioedema rarely responds to these treatments. For ACE inhibitor–induced angioedema, the treatment is mainly supportive. The medication should be discontinued and the patient instructed not to take any ACE inhibitor in the future. There are reports of FFP being used with success in severe cases of ACE inhibitor–induced angioedema. Theoretically, the medications described for the treatment of HAE, would be effective in ACE inhibitor–induced angioedema, but none of them are FDA approved for use at this time. Initial studies looking at ecallantide have not been promising, but icabiben in phase-2 trials appears to be effective in improving ACE inhibitor–induced angioedema.

Several studies are currently underway to further evaluate the effects of these newer medications on ACE inhibitor–induced angioedema.

**KEY CONCEPTS**

- **Anaphylaxis** is a life-threatening systemic allergic or non-allergic reaction of acute onset and multiorgan involvement; timely recognition and treatment are essential to maximize good outcomes.
- A history of sudden urticarial rash accompanied by respiratory difficulty, abdominal pain, or hypotension, strongly favors the diagnosis of anaphylaxis.
- Epinephrine is the first line treatment in patients with anaphylaxis and should be given immediately.
- There are no absolute contraindications to the use of epinephrine in the setting of anaphylaxis.
- Antihistamines and corticosteroids are second- and third-line agents in the management of anaphylaxis and should not replace or precede epinephrine.
- Consider prolonged observation or admission for patients who (1) experience protracted anaphylaxis, hypotension, or airway involvement; (2) receive IV epinephrine or more than two doses of IM epinephrine; or (3) have poor outpatient social support.
- Patients discharged after an anaphylactic event should be prescribed an EpiPen and instructed on its use, encouraged to develop an emergency action plan, and be referred for appropriate medical follow-up.
- Patients with refractory hypotension may require glucagon (receiving beta-blockage) or a continuous IV epinephrine infusion.
- Non-histaminergic angioedema (nonallergic angioedema) does not typically respond to epinephrine and antihistamines. New drugs, including berinert, icatibant, ecallantide, and Ruconest have been approved for use in HAE. FFP has been used with varying success in HAE, ACID, and ACE inhibitor–induced angioedema.

CHAPTER 109: QUESTIONS & ANSWERS

109.1. Which of the following statements regarding anaphylaxis is true?
A. Atopy is a risk factor for parenteral allergens.
B. Food is the cause in less than 10% of cases.
C. Race and geographic locations are predisposing factors.
D. Radiocontrast media (RCM) occurs in 5% of administrations.
E. The cause is unidentified in 50% of cases.
Answer: E. Food is the cause in one-third of cases, and the cause is not identified in one-third of cases. Race and geographic factors do not predispose. Atopy predisposes to mucosal, but not parenteral, administered allergens. RCM reactions occur in 0.22% of cases, given the hyperosmolar agents, but in only 0.04% of cases using nonionic media.

109.2. The majority of the clinical features of anaphylaxis syndrome are produced by which mediator?
A. Acetylcholine
B. Histamine
C. Leukotrienes
D. Prostaglandins
E. Tumor necrosis factor
Answer: B. Histamine is the predominant chemomediator.

109.3. A 31-year-old man has a history of anaphylaxis to penicillin. His condition warrants administration of a cephalosporin. Which of the following is true?
A. A history of penicillin-induced urticaria carries no cross-reactivity risk.
B. An oral cephalosporin given under supervision is acceptable.
C. Most patients with a penicillin allergy history have a true penicillin allergy.
D. Oral and parenteral cephalosporins carry equal risks.
E. The risk of cephalosporin anaphylaxis is 5% to 10%.
Answer: B. Cephalosporin anaphylaxis after penicillin anaphylaxis is very rare (<1%). Parenteral agents carry a higher risk. Oral cephalosporins are likely to be safe. Penicillin-induced urticaria is a risk factor for an increased likelihood of a cephalosporin allergy. Most patients who report a penicillin allergy can safely use penicillin. Both penicillins and cephalosporins are hapten; they require cross-linkage with a host protein to become antigenic.

109.4. A 26-year-old 70-kg man is undergoing a Bier block for fracture reduction of a right distal radius fracture. Lidocaine 350 mg is used. Three minutes after drug injection, the patient develops wheezing, facial flushing, and mucosal edema. Which of the following statements regarding this scenario is true?
A. Benzodiazepines are the treatment of choice.
B. Bupivacaine was probably inadvertently substituted for lidocaine.
C. Latex allergy to the tourniquet is the most likely etiology.
D. Lidocaine toxicity is the most likely etiology.
E. This is a methylparaben reaction.
Answer: D. Local anesthetic allergies are rare. Systemic effects are not. Many authors doubt that allergies to the amide anesthetics even occur. Methylparaben is a preservative in multidose vials that is structurally related to ester local anesthetics and can produce
allergic reactions. Latex allergies are usually of slower onset and mild. Lidocaine toxicity would generally present with central nervous system (CNS) activation and seizures. Bupivacaine toxicity would present as hypotension and then cardiac collapse. Benzodiazepines may be indicated for lidocaine toxicity, not for signs of anaphylaxis.

109.5. Which of the following statements regarding radiocontrast media (RCM) reactions is true?
A. A 12-hour delay in scanning may be warranted to allow adequate steroid dosing.
B. Only H₁ receptor blockers are likely to have a prophylactic effect.
C. Shellfish allergy is a contraindication to RCM use.
D. The pathophysiology of RCM anaphylaxis is immunologically mediated.
E. The specific RCM used has little bearing on the risk of anaphylaxis.

Answer: A. A delay may be necessary to allow adequate steroid dosing. Nonionic, lower weight agents have a far lower incidence of allergic reactions. Shellfish allergy has no bearing or effect. The mechanism of RCM allergy is nonimmunologic and likely involves direct histamine release and complement activation.

109.6. A 27-year-old woman presents with the acute onset of pruritus, followed by flushing, dyspnea, and vomiting. Physical examination is remarkable for urticaria, tachypnea, tachycardia, hypotension, and bronchospasm. What is the appropriate dose of epinephrine for treatment of acute anaphylaxis?
A. 0.3–0.5 mg IM of 1:1000 concentration in anterolateral thigh
B. 1 mL of 1:1000 epinephrine intravenously
C. 5 mL of 1:10,000 epinephrine locally at the reaction site
D. 2 mL of 1:10,000 epinephrine intravenously every 5 minutes
E. 10 mL of 1:10,000 epinephrine over 10 minutes intravenously

Answer: A. Please refer to Box 109.7.
The skin is composed of three layers: the epidermis, dermis, and subcutaneous layer. The epidermis is a thin layer of stratified squamous epithelium, consisting mainly of keratinocytes, which progress through stages of differentiation as they migrate from the basal to the superficial layer. These layers are the stratum germinativum (base of the epithelium), stratum spinosum, stratum granulosum, and stratum corneum (superficial layer). The epidermis also includes other cells, such as melanocytes and Langerhans cells. Melanocytes produce melanin, which functions to add pigment to the skin and also to absorb ultraviolet radiation. Langerhans cells are a component of the immune system and function in the absorption of ultraviolet radiation and production of vitamin D; sensory nerve endings in skin serve important functions of sensation; and finally, certain cells within the epidermis serve important immunologic functions, including Langerhans cells, lymphocytes, mast cells, and keratinocytes.

The skin serves several important physiologic functions. It acts as a barrier between the internal and external environment. The skin protects from external toxic and infectious materials, and subcutaneous layers. The skin is a thin layer of stratified squamous epithelium, consisting mainly of keratinocytes, which progress through stages of differentiation as they migrate from the basal to the superficial layer. These layers are the stratum germinativum (base of the epithelium), stratum spinosum, stratum granulosum, and stratum corneum (superficial layer). The epidermis also includes other cells, such as melanocytes and Langerhans cells. Melanocytes produce melanin, which functions to add pigment to the skin and also to absorb ultraviolet radiation. Langerhans cells are a component of the immune system and function in the absorption of ultraviolet radiation and production of vitamin D; sensory nerve endings in skin serve important functions of sensation; and finally, certain cells within the epidermis serve important immunologic functions, including Langerhans cells, lymphocytes, mast cells, and keratinocytes.

Clinical Features
A general approach to the unknown rash is listed in Box 110.1.

Important historical information includes the time of onset, duration of symptoms, and relation to any new potential allergens, such as foods, medications, soaps, pets, jewelry, and so on. Information about changes over time should be sought, including whether the rash has progressed, improved, or waxed and waned. Associated pain, pruritus, fever, sexual history, occupation or hobbies should be identified. Relevant past medical history includes medical conditions, skin conditions, medications, illicit drug use, allergies, recent travel, sunlight exposure, and family history.

The physical examination is essential to identifying the cutaneous diagnosis. The examination should be performed with adequate lighting. Primary and secondary lesions, as well as characteristics and patterns of lesions should be identified. Lesions may be palpated wearing gloves to identify texture, blanching, or sloughing characteristics. Nikolsky’s sign may be tested, and when positive, gentle rubbing of the skin results in sloughing of the top layer of the epidermis. For patients with systemic complaints, a thorough visual examination from head to soles of feet should be performed, including skin, mucosa, and genitalia.

Identification and description of lesions is essential. Lesions may be classified as primary or secondary lesions. Primary lesions arise directly as a result of the disease process. Secondary lesions result from subsequent factors, such as scratching, treatment, healing, or complicating infections. Primary and secondary lesions and descriptions are listed in Tables 110.1 and 110.2. The significance of distribution of lesions is outlined in Table 110.3.

Diagnostic Testing
Laboratory testing is unnecessary for most patients with a rash. Specific tests for clinically suspected diseases may be indicated, such as blood tests for secondary syphilis, heterophile antibodies (monospot) for mononucleosis, or throat swabs for rapid testing and culture of group A streptococcus. Adjunctive skin tests may be considered, including potassium hydroxide (KOH) prep, Tzanck smear, gram stain, erythrocyte sedimentation rate (ESR), or biopsy. For the patient with severe systemic illness, a complete blood count, blood cultures, lumbar puncture studies, electrolytes, blood urea nitrogen (BUN), creatinine, glucose, and liver function tests should be considered.

Management
Treatments for dermatologic conditions should address both definitive treatment for underlying disease states and symptomatic treatment. If causative agents are identified, they should be discontinued or eliminated from the environment. Topical or systemic therapies may be indicated for a variety of conditions.

Vehicles for topical dermatologic preparations may be important in the therapeutic effect. Vehicles include creams (water-based emulsion of oil), lotions (water-based suspension of
powder), ointments (oil-based suspension, which improves penetration of the active ingredient), gels (transparent, semi-solid, non-greasy emulsion), foams (helpful for scalp or difficult to reach areas), and pastes (ointment base with powder, stiff consistency). For dry, scaly conditions, emollients such as ointments may be more effective. For moist conditions, a dryer vehicle such as a gel or powder may be preferable. Vehicle components may vary with generic preparations, and it is important to monitor clinical success if generic preparations are prescribed. Communication with the patient about preferences may be important. Patient preference and compliance are closely linked to successful outcomes.

MCP, Metacarpophalangeal.
Topical steroids are commonly used to treat inflammatory dermatologic conditions. Topical steroids have several mechanisms of action, including antiinflammatory effects, antiproliferative effects on fibroblasts and collagen, reduction of leukocyte adhesion to capillaries, reduction of capillary wall permeability, reduction of complement components, and histamine antagonism. Adverse effects may include skin atrophy, striae, acniform lesions, pigment changes, telangiectasia, hypothyroidism, anaphylaxis suppression from systemic absorption, and exacerbation of certain conditions such as fungal infections and viral infections. Topical steroids should be prescribed in the lowest potency and for the shortest duration that is effective for the individual patient. Systemic therapies are appropriate for systemic conditions. Commonly used systemic therapies include oral, intramuscular (IM), or intravenous (IV) steroids, antipruritic agents, antibiotics, antifungal agents, and antiviral agents.

**Disposition**

Most ED patients with dermatologic complaints can be successfully managed as outpatients. Indications for inpatient hospitalization include systemic disorders with dehydration, disorders of thermoregulation, systemic infection or other systemic disorder requiring inpatient management, and inability to care for self or maintain appropriate oral intake. Dermatologic outpatient follow-up or inpatient consultation may be appropriate.

**INFECTION DISORDERS**

**Bacterial Infections**

**Impetigo**

Impetigo is typically caused by *Staphylococcus aureus* and/or β-hemolytic *Streptococcus*. Pediatric patients are commonly affected. Streptococcal impetigo (ecthyma) is found most often on the face and other exposed areas. The eruption often begins as a single pustule but later develops multiple lesions. It begins as 1- to 2-mm vesicles with erythematous margins. When these break, they leave red erosions covered with a golden yellow crust (Fig. 110.1). Lesions may be pruritic but usually are not painful. Regional lymphadenopathy is commonly present. Lesions are contagious among infants and young children and less so in older children and adults. Postpyodermal acute glomerulonephritis is a recognized complication of streptococcal impetigo.

*Staphylococcal* impetigo is differentiated from streptococcal impetigo in that it is more superficial, and there is little surrounding erythema. Other diagnostic considerations are herpes simplex virus (HSV) and inflammatory fungal infections. A Gram stain of the weepy erosion obtained after removal of the crust will reveal gram-positive cocci. Methicillin-resistant *Streptococcus aureus* (MRSA) impetigo is increasingly common. Risk factors include prior infection or colonization with MRSA.

Bullous impetigo is caused by the toxin released by *Staphylococcus aureus*. It is seen primarily in infants and young children. The initial skin lesions are thin-walled, 1- to 2-cm bullae (Fig. 110.2). When these rupture, they leave a thin serous crust and collarette-like remnant of the blister roof at the rim of the crust. The face, neck, and extremities are most often affected. The differential diagnosis includes contact dermatitis, HSV infection, superficial fungal infections, and pemphigus vulgaris. A Gram stain of the fluid from a bulla reveals gram-positive cocci. Cultures are positive in 95% of cases.

Empirical therapy should be instituted with oral or topical antibiotics. Oral antibiotics are indicated for severe or multiple lesions. Topical therapies include either mupirocin or retapamulin. Oral therapies include be a regimen with an agent active against *S. aureus*, such as dicloxacillin or cephalaxin. If MRSA is suspected, doxycycline, clindamycin, or trimethoprim-sulfamethoxazole (TMP-SMX) is recommended.

Therapy for bullous impetigo consists of a systemic antibiotic, such as dicloxacillin, erythromycin ethylsuccinate, or azithromycin. Without treatment, impetigo generally heals within 3 to 6 weeks.

**Folliculitis**

Folliculitis is an inflammation in the hair follicle, usually caused by *S. aureus*. It appears as pustules with a central hair. The lesions are usually on the buttocks and thighs, occasionally in the beard or scalp, and may cause mild discomfort. The differential diagnosis includes acne, keratosis pilaris, and fungal infection. Gram-negative folliculitis with *Pseudomonas aeruginosa* can occur after exposure to infected hot tubs and swimming pools or in individuals taking antibiotics for acne; it can be differentiated from staphylococcal folliculitis by a Gram stain of the lesion.

Treatment with an antiseptic cleanser such as povidone-iodine or chlorhexidine every day or every other day for several weeks is usually adequate. For patients with extensive involvement, a course of systemic antibiotics may be added, such as doxycycline or dicloxacillin.

**Cellulitis**

Cellulitis presents with localized erythema, swelling, and pain of the soft tissues (Fig. 110.3). Erysipelas is a streptococcal infection...
of the skin and subcutaneous tissue. Systemic symptoms may include fever, myalgias, and malaise. Cellulitis may be a cause of sepsis. Ultrasound may be helpful in differentiating abscess, which appears as a fluid filled cavity, from cellulitis, which appears as cobblestoning, with fine reticular areas of hypoechoic stranding.

Mild cases of cellulitis may be treated with an oral antibiotic, such as penicillin VK, a cephalosporin, dicloxacillin, or clindamycin. Severe cases should be treated with IV vancomycin plus piperacillin/tazobactam. Necrotizing fasciitis and emergent surgical consultation should be considered.

Soft tissue skin infections are discussed in more depth in Chapter 129.

Abscesses may present with localized soft tissue swelling, erythema, and fluctuance (Fig. 110.4). Ultrasound may be helpful in differentiating abscess, which appears as a fluid filled cavity from cellulitis, which appears as cobblestoning, with fine reticular areas of hypoechoic stranding. Mild abscesses require incision and drainage alone. Recent literature suggests higher cure rate for antibiotic treatment with TMP-SMX in addition to incision and drainage. Moderate or severe abscesses should have culture and sensitivity performed. Empirical antibiotic therapy may be added, with agents such as TMP-SMX or doxycycline. If IV antibiotics are indicated, agents may include vancomycin, daptomycin, linezolid, televacine, or ceftaroline.

Hidradenitis suppurativa affects the apocrine sweat glands. Recurrent abscess formation in the axillae and groin resembles localized furunculosis. The condition tends to be recurrent and may be extremely resistant to therapy. Ultrasound will help differentiate abscesses from vascular or lymphoid structures. Hidradenitis suppurativa may be treated with drainage of abscesses if they are fluctuant, painful, and large. Antistaphylococcal antibiotics are useful if they are administered early and for a prolonged period. Begin treatment for mild disease with topical clindamycin for 3 months. In patients with more severe or nonresponsive disease, begin oral clindamycin combined with rifampin for 3 to 6 months. Antiandrogen therapy may be considered if antibiotics do not produce improvement. Many cases do not respond, however, and eventually require local excision and skin grafting of the involved area.

Carbuncle

A carbuncle is a large abscess that develops in the thick, inelastic skin of the back of the neck, back, or thighs and usually involves hair follicles. Carbuncles may produce severe pain and fever. Septicemia may accompany the lesions. The diagnosis of skin abscess, furuncle, or carbuncle is usually made clinically. Ultrasonography is often helpful in diagnosis of carbuncles or abscesses that may not appear fluctuant on examination.

Local heat should be applied to furuncles and carbuncles, which should be incised and drained when fluctuant. Antibiotics are unnecessary with incision and drainage unless cellulitis or septicemia is present.

Methicillin-Resistant *Staphylococcus Aureus*

The incidence of community-associated MRSA has soared since the first report in 1993. In many major cities in the United States, MRSA is now the most common pathogen cultured from ED patients presenting with skin and soft tissue infections. Concern exists that MRSA may be more virulent than methicillin-sensitive strains, and colonization with MRSA may produce more overt infections. Hospital-acquired MRSA isolates can survive on a variety of inanimate surfaces, sometimes for weeks. It is unclear whether this is also true for community acquired MRSA isolates; if it is true, their presence on such items as clothing, towels, and athletic equipment might contribute to outbreaks. Pets (including dogs and cats), livestock, and birds have been identified as MRSA carriers; their role in MRSA transmission to humans is unclear.

MRSA infections are most often manifested as skin and soft tissue suppuration, such as an abscess, furuncle, or cellulitis. Lesions frequently exhibit central necrosis and are often confused with spider bites by patients. Clinical features cannot distinguish with certainty skin and soft tissue infections caused by MRSA from those caused by methicillin-susceptible *S. aureus*. Although rare, MRSA infection can also be manifested as necrotizing fasciitis. Recurrences of MRSA cellulitis are common. Contagion among the close household contacts of patients as well as correctional facility, school, and sports team contacts is well recognized.

Several studies have demonstrated excellent outcomes for abscesses caused by MRSA that are treated with incision and drainage alone. Antimicrobial therapy is recommended in addition to incision and drainage for patients with severe or extensive disease, rapid progression in presence of associated cellulitis, systemic illness, associated comorbidities or immunosuppression, extremes of age, abscess in an area difficult to drain, associated septic phlebitis, and lack of response to incision and drainage alone.
If local resistance patterns are known, they should guide antimicrobial choice. Clindamycin combines MRSA activity with effectiveness against the majority of other gram-positive organisms. A recent study found no significant difference between the efficacy of clindamycin and TMP-SMX for the treatment of uncomplicated skin infections, including both cellulitis and abscesses. Rifampin has anti-MRSA activity, but resistance readily develops, so it should not be used as monotherapy. Linezolid is active against almost all MRSA isolates and group A streptococci. Disadvantages of its use include high cost, lack of routine availability, hematologic side effects, and potential for resistance among *S. aureus* strains. Prolonged linezolid administration increases the likelihood of resistance. Other agents effective against MRSA include TMP-SMX, minocycline, or doxycycline. Cephalexins and macrolides are typically ineffective against MRSA. Fluoroquinolones should be avoided because *S. aureus* resistance develops readily.

Patients with large abscesses, abscesses in high-risk locations, fever, signs of systemic infection, young age, or immunodeficiency prompt consideration of hospitalization. Vancomycin is considered the parenteral drug of choice for patients with invasive *S. aureus* infection, although clinical failures have been reported. It is reasonable to combine vancomycin with another effective antistaphylococcal agent because many antibiotics have better bactericidal activity. In severely ill patients, carbapenems such as meropenem, panipenem, and ertapenem are recommended, because they are active against MRSA and synergistic with vancomycin. Other effective parenteral agents may include clindamycin, linezolid, daptomycin, tigecycline, or telavancin.

Recurrent infections are generally treated like initial episodes. Although “decolonization” strategies have been recommended, neither the indications for their use nor their effectiveness in reducing the risk of recurrences is established. Decolonization strategies include the use of intranasal mupirocin to reduce nasal carriage of MRSA; however, eradication of nasal colonization appears to be transient.

Common antiseptics appear to retain reasonable activity against MRSA, although the results of studies are somewhat conflicting. Good personal hygiene, including appropriate handwashing techniques, separation of infected patients from other types of patients, and routine cleaning of shared equipment, are essential to limiting MRSA spread.

Erythema Migrans

Lyme disease is caused by the organism *Borrelia burgdorferi* and is transmitted by the deer tick bite (Fig. 110.5). Most cases occur in the spring and early summer. Endemic areas in the United States include the Northeast, Midwest, West, and scattered other areas. Although 36 to 48 hours of tick attachment is necessary to transmit disease, less than 33% of patients recall a tick bite. The incubation period is 3 to 30 days.

Clinical presentations include three disease stages. Stage I occurs early and is manifested by malaise, headache, fever, lymphadenopathy, and arthralgias. Stage I typically resolves in 4 weeks. Erythema migrans occurs in 60% to 80% of cases and manifests as erythematous annular, non-scaling lesion with central clearing (Fig. 110.6). Stage II presents with secondary annular lesions, fever, lymphadenopathy, neurologic manifestations, or cardiac conduction abnormalities that may last weeks to months. Stage III manifests as chronic arthritis, dermatitis, and central nervous system (CNS) disease.

Diagnostic tests may include a nonspecific elevated ESR and serologic tests, which are helpful in establishing the definitive diagnosis but are not available acutely.

Management should include appropriate antibiotic administration. The antibiotic regimen may include doxycycline for 10 to 21 days, or as alternates, cefuroxime, ceftriaxone, or penicillin G. Amoxicillin may be used in pediatric and pregnant patients.

An in depth discussion of Lyme disease can be found in Chapter 126.

Necrotizing Fasciitis

Necrotizing fasciitis should be considered with skin and soft tissue infection with signs of systemic toxicity, or severe infection (Figs. 110.7, 110.8, and 110.9). Prompt surgical consultation is recommended. Empirical antibiotic treatment should be instituted with broad coverage (eg, vancomycin or linezolid plus piperacillin-tazobactam or a carbapenem; or plus ceftriaxone and metronidazole), because the etiology can be polymicrobial (mixed aerobic/anaerobic microbes) or monomicrobial (group A streptococci, community-acquired MRSA). An in depth discussion of necrotizing fasciitis can be found in Chapter 129.

Meningococcal Infection

Meningococcal infection is caused by the organism *Neisseria meningitides*, typically transmitted by respiratory secretions.
Clinical presentation may include fever, malaise, arthralgias, nausea, and vomiting. Cutaneous findings of macules, papules, vesicles, or petechiae and purpura may be present. Ten percent of cases may present with Waterhouse-Friderichsen syndrome characterized by shock with intracutaneous hemorrhage.

An in depth discussion of meningococcal disease can be found in Chapter 121. The diagnosis should be suspected clinically in the ED setting and treated promptly. Confirmatory tests may include blood cultures, cerebrospinal fluid (CSF) cultures, or skin scrapings. Rapid administration of antibiotics is essential. Empirical therapy should be instituted with agents, such as a third generation cephalosporin (eg, ceftriaxone or cefotaxime) plus vancomycin. Alternative antibiotics may include penicillin G, chloramphenicol, a fluoroquinolone, or aztreonam. Dexamethasone should also be considered for suspected or proven meningitis. Immunization against meningococcal infection is recommended for groups at increased risk for infection, including adolescents and persons at risk for exposure.

Scarlet Fever
Scarlet fever results from group A strep infection. The illness has an abrupt onset with fever, chills, malaise, and sore throat, followed within 12 to 48 hours by a distinctive rash that begins on the chest and spreads rapidly, usually within 24 hours. Circumoral pallor may be noted. The skin has a rough sandpaper-like texture because of the multitude of pinhead-sized lesions. The pharynx is injected, and there may be erythematous lesions or petechiae on the palate. After the resolution of symptoms, desquamation of the involved areas occurs and is characteristic of the disease. Erythema marginatum may be seen in 10% of cases and presents with annular erythematous lesions that may be transient and reappear over days, weeks, or months (Fig. 110.10).

Complications include the development of a streptococcal infection of lymph nodes, tonsils, middle ear, and respiratory tract. Late complications include rheumatic fever and acute glomerulonephritis.

Treatment is with oral penicillin VK or IM benzathine penicillin (given as Bicillin C-R). In patients allergic to penicillin, treatment may be initiated with erythromycin, other macrolides, or a cephalosporin.

Syphilis
Syphilis is the third most common sexually transmitted infection in the United States (following chlamydia and gonorrhea) and is...
transmitted by direct contact with an infectious lesion. The causative organism is the spirochete *Treponema pallidum*. After an incubation period of 10 to 90 days, the primary lesion appears, which lasts 3 to 12 weeks and heals spontaneously. In 6 weeks to 6 months after exposure, the secondary stage appears, which involves a variety of mucocutaneous lesions. These lesions also heal spontaneously in 2 to 6 weeks as the disease enters the latent phase. Either a prolonged latent phase or tertiary syphilis follows. Among untreated patients, 25% display at least one relapse of mucocutaneous lesions of the oral cavity or anogenital region.

The chancre is the dermatologic manifestation of primary syphilis. Chancres usually appear as single lesions but may be multiple. They appear at the site of spirochete inoculation, usually the mucous membranes of the mouth or genitalia. The chancre begins as a papule and characteristically develops into an ulcer approximately 1 cm in diameter with a clean base and raised borders (Fig. 110.11). The chancre is painless unless it is secondarily infected, and it may be accompanied by painless lymphadenopathy. Many patients do not recall the primary chancre.

The secondary stage usually follows the primary stage by 6 weeks or more but rarely overlaps primary syphilis. There are a number of cutaneous manifestations of secondary syphilis. Lesions may be erythematous or pink macules or papules, usually with a generalized symmetric distribution. Secondary syphilis should be considered in the differential diagnosis of any maculopapular rash. Pigmented macules and papules may appear on the palms and soles (Fig. 110.12). Generalized lymphadenopathy and malaise accompany the skin lesions. Moist, flat, verrucous condyloma latum may appear in the genital area. These lesions are highly contagious.

The diagnosis of primary or secondary syphilis should be made in the ED based on clinical presentation. Definitive diagnosis is made by the identification of spirochetes with darkfield microscopy and by serologic testing. The result of the Venereal Disease Research Laboratory (VDRL) test, the most commonly used diagnostic serologic test, is positive in approximately three-fourths of patients with primary syphilis, but may be negative early in the course of the disease. The VDRL test result is invariably positive in cases of secondary syphilis, usually in titers of 1:16 or greater. The most specific and sensitive serologic test is the fluorescent treponemal antibody absorption (FTA-ABS) test. A biologic false-positive serologic test response for syphilis is defined as a positive VDRL test result with a negative FTA-ABS test result. This situation is seen acutely after vaccination or infections, especially mycoplasmal pneumonia, mononucleosis, hepatitis, measles, varicella, and malaria, and in pregnancy. Chronic biologic false-positive reactions (ie, those lasting longer than 6 months) may occur with systemic lupus erythematosus, thyroiditis, lymphoma, and narcotic addiction or in elderly patients. Most false-positive reactions are in low titer ranges of 1:1 to 1:4.

Guidelines for syphilis treatment, including in penicillin allergic individuals, are available at www.cdc.gov. Primary and secondary syphilis is treated with benzathine penicillin G in a dose of 2.4 million units IM. Human immunodeficiency virus (HIV)-infected patients require more intensive therapy. Patients with latent syphilis are treated the same as patients with primary disease; latent syphilis and tertiary syphilis are treated with benzathine penicillin G, three doses of 2.4 million units IM at weekly intervals for a total of 7.2 million units. Treatment of neurosyphilis requires infusion of aqueous crystalline penicillin, 3 to 4 million units IV every 4 hours for 10 to 14 days. Within 12 hours of receiving therapy, patients may experience a febrile reaction and diffuse rash called the Jarisch-Herxheimer reaction; thus it is best to warn patients of this possibility. The reaction resolves spontaneously, usually within 24 hours.

Treatment may be administered in the ED if the diagnosis can be made on clinical, microscopic, or serologic grounds. If this cannot be done, a serologic sample should be drawn and the patient referred for treatment. The VDRL test response may be expected to return to nonreactive 6 to 12 months after the treatment of primary disease or 1 to 1½ years after the treatment of secondary disease. Patients with tertiary syphilis who are adequately treated may nevertheless retain a positive serologic result.

An in depth discussion of syphilis can be found in Chapter 88.

**Gonococcal Dermatitis**

The arthritis-dermatitis syndrome is the most common presentation of disseminated gonococcal disease. It occurs in less than 2% of patients with gonorrhea, affecting women primarily. Fever and migratory polyarthralgias commonly accompany the skin lesions. The lesions are often multiple and have a predilection for periaricular regions of the distal extremities. The lesions begin as erythematous or hemorrhagic papules that evolve into pustules and vesicles with an erythematous halo (Fig. 110.13). They may be tender and may have a gray necrotic or hemorrhagic center. Healing with crust formation usually occurs within 4 or 5 days,
although recurrent crops of lesions may appear even after antibiotics have been started.

The organism may be cultured from the cutaneous lesions. Gram stain only occasionally reveals the organisms. A more reliable diagnostic technique is immunofluorescent antibody staining of direct smears from pustules. This method indicates that the lesions may be the result of hematogenous dissemination of non-viable gonococci.

Current treatment of disseminated gonococcal infection is with parenteral ceftriaxone, or cefixime or cefotaxime. Patients allergic to β-lactam antibiotics or those with severe penicillin allergies may be treated with spectinomycin. Ciprofloxacin and ofloxacin are not recommended because of increasing resistance patterns. Hospitalization is recommended for patients with disseminated gonococcal infection.

An in depth discussion of gonococcal disease can be found in Chapter 88.

Staphylococcal Scalded Skin Syndrome
Staphylococcal scalded skin syndrome (SSSS) generally occurs in children 6 years old or younger. It is caused by an infection with phage group 2 toxin-producing staphylococci. The illness begins with erythema and crusting around the mouth. The erythema then spreads down the body, followed by bulla formation and desquamation. Mucous membranes are usually typically involved. After desquamation occurs, the lesions dry up quickly, with clinical resolution in 3 to 7 days.

Most group 2 toxin-producing organisms are penicillin resistant. Although most patients will recover without antibiotic treatment, IV therapy with nafcillin, cephalaxin, or dicloxacillin is recommended. Clindamycin, vancomycin, linezolid, and imipenem, meropenem, ticarcillin–clavulanate, or piperacillin–tazobactam may be considered in cases of suspected MRSA.

An in depth discussion of suspected MRSA.

Toxic Shock Syndrome
Toxic shock syndrome (TSS) is an acute febrile illness characterized by a diffuse desquamating erythroderma. Clinical presentation may include high fever, hypotension, constitutional symptoms, multiorgan involvement, and rash. The syndrome gained notoriety in the early 1980s because of association with tampon use. However, it is also well known in men and children. Its appearance has often been linked to exotoxin-producing S. aureus. Approximately 50% of cases are associated with menstruation. Other cases occur in the postoperative setting, burns, postpartum infection, osteomyelitis, arthritis, empyema, fasciitis, septic abortion, peritonitis, abscess, sinusitis, and subcutaneous abscess.

TSS is caused by S. aureus or group A streptococcus, also called Streptococcus pyogenes. It has been reported in previously healthy patients, immunocompromised patients, and elders. Fatigue, localized pain, and nonspecific symptoms herald the onset of this disease, followed by septic shock and multisystem organ failure.

Diagnosis of TSS requires the presence of (1) temperature of at least 38.9°C; (2) hypotension, with a systolic blood pressure of 90 mm Hg or less; (3) rash; and (4) involvement of at least three organ systems. Systemic involvement may include the gastrointestinal tract, muscular system, or CNS and laboratory evidence of renal, hepatic, or hematologic dysfunction. Headache, myalgias, arthralgia, alteration of consciousness, nausea, vomiting, and diarrhea may be present.

The rash is typically a diffuse, blanching, macular erythroderma. Accompanying nonexudative mucous membrane inflammation is common. Pharyngitis, sometimes accompanied by a "strawberry tongue," conjunctivitis, or vaginitis, may be seen. As a rule, the rash fades within 3 days of its appearance. This is followed by a full-thickness desquamation, most commonly involving the hands and feet.

Initial treatment of TSS consists of IV fluid replacement, ventilatory support, pressor agents, antibiotics covering S. aureus (including MRSA) and S. pyogenes. Initial empirical antibiotic regimens may include clindamycin, vancomycin, linezolid, imipenem, meropenem, ticarcillin–clavulanate, or piperacillin–tazobactam.

An in depth discussion of TSS can be found in Chapter 129.

Rocky Mountain Spotted Fever
Rocky Mountain spotted fever is caused by Rickettsia rickettsii, an organism harbored by a variety of ticks. The organism is transmitted to humans through tick saliva at the time of a tick bite or when the tick is crushed while in contact with the host. Many patients do not report tick exposure. Although originally described in the Rocky Mountain region, this disease occurs in other areas of North, South, and Central America. Most reported cases are from the southeastern United States.

The onset of the illness is usually abrupt, with headache, nausea and vomiting, myalgias, chills, and fever. On occasion, the onset is more gradual, with progressive anorexia, malaise, and fever. The disease may last 3 weeks and may be severe with prominent involvement of the CNS, cardiac, pulmonary, gastrointestinal and renal systems, disseminated intravascular coagulation, or shock.

The rash develops on the second to sixth day. It begins with erythematous macules that blanch on pressure, appearing first on the extremities and trunk and face. They may become petechial or hemorrhagic (Fig. 110.14). Lesions on the palms and soles are particularly characteristic. Increased capillary fragility and splenomegaly may be present.

The rash fades within 3 days of its appearance. This is followed by a full-thickness desquamation, most commonly involving the hands and feet.

Fig. 110.13. Disseminated gonorrhoea. (Courtesy David Effron, MD.)
fever clinically and is also reliably treated with doxycycline. Chloramphenicol efficacy in this disease is not established.

An in depth discussion of Rocky Mountain spotted fever can be found in Chapter 126.

Viral Infections

Herpes Simplex Virus

Two known variants of HSV cause human infection: HSV-1 and HSV-2. HSV-1 primarily affects nongenital sites, whereas lesions caused by HSV-2 are found predominantly in the genital area and are typically transmitted primarily by sexual contact.

The characteristic presentation of skin infection with HSV is painful, grouped vesicles on an erythematous base (Fig. 110.15). The lesions are usually localized in a nondermatomal distribution. The skin distribution may become more generalized in patients with atopic dermatitis and other dermatoses. Adults with HSV infection should avoid contact with children with atopic dermatitis, especially in the first 3 to 5 days of infection.

The mouth is the most common site of HSV-1 infections. Children are affected more commonly than adults. Small clusters of vesicles appear but are soon denuded, leaving irregularly shaped, crusted erosions. The severity of gingivostomatitis varies from the presence of small ulcers to extensive ulceration of the mouth, tongue, and gums accompanied by fever and cervical lymphadenopathy (Fig. 110.16). The infection may be so severe that oral fluid intake is difficult, and dehydration may result. Healing typically occurs in 7 to 14 days unless a secondary bacterial infection occurs.

Herpetic whitlow is a herpes infection of the hand, typically affecting the distal phalanx (Fig. 110.17). It may be caused by HSV-1 (60%) and HSV-2 (40%). HSV-2 infections in men present with either single or multiple vesicles on the penile shaft or glans penis. Fever, malaise, and regional adenopathy may be present. A prodrome of local pain and hyperesthesia may precede the appearance of the cutaneous lesions. The vesicles erode after several days, become crusted, and heal in 10 to 14 days. Infections in women involve the introitus, cervix, or vagina. Vesicles may be grouped or confluent. Herpetic cervicitis or vaginitis may be the cause of severe pelvic pain, dysuria, or vaginal discharge. Recurrence is common, but recurrent episodes tend to be less severe. A correlation based on serologic and epidemiologic data has been discovered between HSV-2 reproductive tract infections and carcinoma of the cervix.

Recommended treatment for a first clinical episode of genital herpes is with acyclovir, famciclovir, or valacyclovir. These agents reduce the duration of viral shedding, accelerate healing, and shorten the duration of symptoms, but they do not prevent recurrent episodes. Prophylactic administration of acyclovir may be effective in ameliorating the severity of recurrent genital herpes, but the effects of long-term administration are unknown.
IV therapy should be considered for immunocompromised patients. A mucocutaneous herpes infection in such patients is potentially fatal, because it has a propensity for generalization and dissemination to the internal organs.

Any vesicular eruption on skin or mucous membranes in a neonate should prompt concern for HSV infection, because there is a high likelihood of dissemination in this group. Unless an alternative diagnosis is established, urgent testing of the vesicle fluid for HSV along with acyclovir therapy is indicated.

Supportive care and pain control are important components of treatment. Systemic analgesics and topical anesthetic agents may be useful. Education of the patient about the prevention or spread of the disease during sexual contact and the birth process is imperative.

An in depth discussion of HSV infection can be found in Chapter 122.

Varicella-Zoster Virus

Varicella. Varicella, or chickenpox, is an infection caused by the varicella-zoster virus. After an incubation period of 14 to 21 days, the illness begins with a low-grade fever, headache, and malaise. The exanthem coincides with these symptoms in children and follows them by 1 or 2 days in adults.

The skin lesions rapidly progress from macules to papules to vesicles to crusting, sometimes within 6 to 8 hours. The vesicle of varicella is 2 or 3 mm in diameter and surrounded by an erythematous border (Fig. 110.18). An unusual form of varicella has larger bullae. The drying of the vesicle begins centrally, producing umbilication. The dried scabs fall off in 5 to 20 days.

Lesions appear in crops on the trunk, where they are seen in the highest concentration, and on the scalp, face, and extremities. The hallmark of varicella is the appearance of lesions in all stages of development in one region of the body. Extensive eruptions are often associated with a high and prolonged fever.

Complications include encephalitis or meningitis, pneumonia, staphylococcal or streptococcal cellulitis, thrombocytopenia, arthritis, hepatitis, and glomerulonephritis. Varicella pneumonia occurs more commonly in adults than in children.

Herpes Zoster. Herpes zoster, or “shingles,” is an infection caused by the varicella-zoster virus. It occurs exclusively in individuals who have previously had chickenpox. Dermatomal pain may precede the eruption by 1 to 10 days and is variable in intensity; it may be described as sharp, dull, or burning in quality. The rash consists of grouped vesicles on an erythematous base involving one or several dermatomes. The thorax is involved in most cases, and the trigeminal distribution is the next most commonly involved region.

The vesicles initially appear clear and then become cloudy and progress to scab and crust formation. This process takes 10 to 12 days, and the crusts fall off in 2 or 3 weeks (Fig. 110.19). Herpes zoster has a peak incidence in patients 50 to 70 years old and is unusual in children. Although the association with leukemia, Hodgkin’s lymphoma, and other malignant neoplasms is well known, rarely does the appearance antedate the diagnosis of such diseases. Most cases of herpes zoster occur in healthy individuals.

Herpes zoster may be transmitted from patients with chickenpox to susceptible individuals. Chickenpox may also be acquired by contact with shingles, although this is less common. It is generally believed, however, that herpes zoster is caused by a
reactivation of latent varicella-zoster virus present since the initial infection. During the latent period between the two illnesses, the virus is thought to reside in dorsal root ganglion cells.

Herpes zoster has a very low mortality rate and is rarely life-threatening, except when dissemination to the visceral organs occurs. Complications include CNS involvement, ocular infection, and neuralgia. Meningoencephalitis, myelitis, and peripheral neuropathy have been reported.

Ocular complications occur in 20% to 70% of cases involving the ophthalmic division of the trigeminal nerve. The severity varies from mild conjunctivitis to panophthalmitis, which threatens the eye. Corneal dendritic lesions may be visible on fluorescein examination. Eye involvement may produce anterior uveitis, secondary glaucoma, and corneal scarring. There is a close correlation between eye involvement and vesicles located at the tip of the nose (Hutchinson’s sign).

Herpes zoster generally tends to be more severe in immunosuppressed patients, especially those with acquired immunodeficiency syndrome (AIDS), Hodgkin’s disease, or other lymphomas. Cutaneous dissemination occurs more commonly in these patients than in the general population. Visceral and CNS dissemination is also more likely to occur in these patients; therefore, they should be considered for hospitalization.

Antiviral medications are indicated, especially within 48 hours of onset of rash, to decrease the duration of symptoms and associated pain. Antiviral therapy may be initiated with acyclovir, famciclovir, or valacyclovir. Supportive care is important for pain and pruritus control. Burrow’s solution compresses diluted 1:20 to 1:40 in water may be applied to hasten drying. The administration of corticosteroids is controversial. Steroids may reduce pain and improve sleep and ability to function. Steroids have not been shown to reduce the incidence of postherpetic neuralgia.

IV administration of acyclovir may be of some benefit in the treatment of severe ocular herpes zoster. Treatment includes mydriasis and the application of topical corticosteroids. Unlike the situation with herpes simplex conjunctivitis, eye involvement caused by herpes zoster does not appear to be exacerbated by corticosteroids. Immunization against herpes zoster is recommended in older adults.

Postherpetic neuralgia may occur in 15% of patients and is more commonly in the elderly. Treatments may include opioids, amitriptyline, topical capsaicin, topical lidocaine, topical or oral gabapentin.

The varicella vaccine has been shown to boost immunity against herpes zoster virus (shingles) and is recommended for patients 60 years old and older. It reduces the occurrence of shingles and also slightly reduces pain compared with no vaccination in those who ultimately develop shingles.

An in depth discussion of herpes zoster infection can be found in Chapter 122.

Viral Exanthems

An exanthem is defined as a skin eruption that occurs as a symptom of a general disease. In the pediatric population, 72% of cases of fever and rash are caused by viruses, and 20% are caused by bacteria. Approximately 30 enteroviruses, predominantly the coxsackievirus and echovirus groups, and four types of adenoviruses are known to produce exanthems (Fig. 110.20). The exanthems of the coxsackievirus and echovirus are most thoroughly documented. Most viral exanthems are maculopapular, although scarlatiniform, erythematous, vesicular, and petechial rashes are occasionally seen. The eruptions are variable in their extent, are nonpruritic, and do not desquamate. Oropharyngeal lesions may be present.

The classic viral exanthems are rubella (measles), rubella (German measles), herpesvirus 6 (roseola), parvovirus B19 (erythema infectiousum or fifth disease), and the enteroviruses (echovirus and coxackievirus). Widespread immunization programs have reduced the incidence of rubeola and rubella.

An in depth discussion of viral infections can be found in Chapter 122.

Roseola Infantum. Roseola infantum, otherwise known as exanthem subitum or sixth disease, is a benign illness caused by human herpesvirus 6 and human herpesvirus 7 and is typically spread by saliva. It is characterized by fever and a skin eruption. Ninety-five percent of cases are seen in children 6 months to 3 years old. A febrile seizure may occur. The fever typically has an abrupt onset, with temperature rising rapidly to 39° or 41° C, and is present consistently or intermittently for 3 or 4 days, at which time the temperature drops precipitously to normal. The rash typically appears with defervescence. The lesions are discrete pink or rose-colored macules or maculopapules 2 or 3 mm in diameter that blush on pressure and rarely coalesce (Fig. 110.21). The trunk is involved initially, with the eruption typically spreading to the neck and extremities. The eruptions are occasionally limited to the trunk. The rash clears during 1 or 2 days without desquamation.

Despite the presence of a high fever, the infant usually appears well. Encephalitis is a very rare complication. The prognosis is excellent, and no treatment is necessary.

Measles. Measles, or rubeola, is a highly contagious viral illness spread by contact with infectious droplets, with an incubation period of 10 to 14 days. In recent years, typically less than 100 cases are seen annually in the United States, compared to the 4 to 5 million cases per year prior to immunization. An outbreak in 2014 was seen in the United States, with over 500 cases. Measles is most likely to infect unvaccinated individuals, often including preschoolers in low-income homes or in heavily populated areas. Patients are considered to be contagious from 5 days prior to onset of symptoms until 5 to 6 days after the onset of dermatologic involvement.

Symptoms begin with fever and malaise. The fever usually increases daily in a stepwise manner until the fifth or sixth day of
the illness. Cough, coryza, and conjunctivitis are associated symp-
toms. On the second day of the illness, Koplik spots, which are pathognomonic of the disease, appear on the buccal mucosa as small, irregular, bright red spots with bluish white centers. Begin-
ning opposite the molar, Koplik spots may spread to involve a variable extent of the oropharynx.

The cutaneous eruption of measles typically begins on the third to fifth day of the illness. Maculopapular erythematous lesions involve the forehead and upper neck and spread to involve the face, trunk, arms, and finally the legs and feet. Koplik spots begin to disappear coincident with the appearance of the rash. By the third day of its presence, the rash begins to fade, doing so in the order of its appearance, and the fever subsides.

Complications may include otitis media, encephalitis, and pneu- monitis. Otitis media is the most common complication. Encephalitis occurs in approximately 1 in 1000 cases of measles and carries 15% mortality. Measles pneumonia may also be life-threatening.

Treatment is primarily supportive and should include anti-
pyretics, hydration, and treatment of pruritus. Vitamin A supple-
ments have been associated with reductions of approximately 50% in morbidity and mortality and appear to help prevent eye
damage and blindness. If bacterial invasion occurs with otitis or pneumonia, the use of antibiotics is indicated. Isolation of infected children is of limited value because exposure usually occurs before the appearance of the rash. Measles is not contagious after the fifth day of the presence of the rash. Infection confers lifelong immunity.

Postexposure prophylaxis may be administered with the measles virus vaccine or human immunoglobulin.20

Rubella. Rubella, or German measles, is a viral illness char-
acterized by fever, skin eruption, and generalized lymphadenopa-
thy. It is spread by droplet contact, and peak incidence is in the winter and early spring. The incubation period is typically 14 to 21 days, and the rash heralds the onset of the illness in children. The maximum time of communicability is in the few days before and 5 to 7 days after the onset of the rash. Infants with congenital rubella may shed virus for more than 1 year. In adults, a 1- to 6-day prodrome of headache, malaise, sore throat, coryza, and low-grade fever precedes the rash. These symptoms generally disappear within 24 hours after the appearance of the skin eruption.

The rash of pink to red maculopapules appears first on the face and spreads rapidly to the neck, trunk, and extremities. Those on the trunk may coalesce, but lesions on the extremities do not. The rash remains for 1 to 5 days, classically disappearing at the end of 3 days. Although clearing may be accompanied by fine desquama-
tion, this sign is usually absent.

The major complications of rubella include encephalitis, arthritis, and thrombocytopenia. The most severe complication is fetal damage. A total of 24% of infected fetuses have a congenital defect. A maternal infection may be determined by obtaining serum for hemagglutination inhibition antibody determinations, acutely and in 7 to 21 days after the first sample onset. A fourfold rise in the titer is diagnostic of rubella infection.

No treatment is required in most cases of rubella. Antipyretics are usually adequate for the treatment of headache, arthralgias, and painful lymphadenopathy.

Erythema Infectiosum. Erythema infectiosum, or “fifth disease,” is caused by parvovirus B19 infection and typically affects pediatric patients. It is characterized by mild systemic symptoms, fever in 10% to 15% of patients, and a characteristic rash. Arthral-
gia and arthritis occur commonly in adults but rarely in children. The rash is intensely red on the face and gives a “slapped-cheek” appearance with circumoral pallor. A reticular maculopapular eruption, which may be noted on the arms, moves caudally to the trunk, buttocks, and thighs. The rash may recur with changes in temperature and exposure to sunlight. The incubation period is usually between 4 and 14 days. The infection is benign and requires supportive care only.

Fungal Infections

Fungal infections may affect the skin, scalp, or mucous mem-
branes. The dermatophyoses are superficial fungal infections that are limited to the skin. Dermatophytes generally grow best in warm, moist environments, and grow only in the keratin or outer layer of the skin, nails, and hair. Any potential dermatophyte infection can be examined under the microscope in a KOH prepar-
ation. The specimen is examined for the characteristic branching
hyphae of the dermatophytes or the short, thick hyphae and clustered spores of tinea versicolor.

Tinea Corporis

Tinea refers to superficial dermatophytic infection of the skin, hair, and/or nails, usually by the Trichophyton organism. Tinea corporis, commonly referred to as “ringworm” infection, presents as a sharply marginated, annular lesion with raised or vesicular margins and central clearing (Fig. 110.22). Lesions may be single or multiple. Other related forms of tinea may be seen, including tinea cruris, which involves the groin, tinea manuum, affecting the hands, and tinea pedis, infection of the feet.

The differential diagnosis of tinea corporis includes erythema migrans, granuloma annulare, psoriasis, cellulitis, and erythrasma.

Infections of the body, groin, and extremities usually respond to topical antifungal agents. A number of effective topical antifungal agents are available, including clotrimazole, haloprogin, miconazole, tolnaftate, terbinafine, naftifine, and others. Two or three daily applications of the cream form of any of these preparations result in healing of most superficial lesions in 1 to 3 weeks.21
African Americans, for uncertain reasons. Nosocomial transmission of dermatophyte infections, such as *Trichophyton tonsurans*, has also been reported. Alopecia may be seen, typically with thickened, scaly scalp. Broken hairs resembling black dots near the scalp may be seen. Hair loss is the result of hyphae growing within the hair shaft, rendering it fragile, so that the hair strands break off 1 to 2 mm above the scalp. The disease may be transmitted by close child-to-child contact and contact with household pets, hats, combs, barber’s shears, and similar items. Complications may include kerion formation, lymphadenitis, bacterial pyoderma, pigmenting pityriasis alba, and Langerhans cell histiocytosis.

The differential diagnosis of tinea capitis includes alopecia areata, atopic dermatitis, nummular eczema, bacterial infection, psoriasis, seborrheic dermatitis, “tinea” amiantacea, trichotillomania (hair pulling), and Langerhans cell histiocytosis.

A KOH preparation is not helpful in the presence of a kerion or in the absence of alopecia. The diagnosis is typically made based on clinical presentation. If in question, a fungal culture specimen may be obtained.

Systemic therapy is required for tinea capitis, due to fungal invasion of the hair follicles. Treatment should be with a systemic antifungal agent, such as terbinafine or griseofulvin. Therapy should be given for 4 to 6 weeks. The patient should be referred for outpatient follow-up with primary care within 4 weeks. Alternative therapy includes fluconazole or itraconazole for 4 to 6 weeks. Family members should be evaluated for possible infection.

**Kerion**

A kerion is a fungal infection affecting hair follicles that is characterized by intense inflammation, and a boggy, erythematous mass, typically affecting the scalp (Fig. 110.23). The lesion may contain frank pus. The inflammation is generally uniform and does not display satellite lesions. It usually affects the scalp and is more common in children and in African Americans. Local alopecia and scarring can ensue. Lymphadenopathy may be present. Accurate differentiation of a kerion with and without superinfection can be challenging. Wood’s lamp examination and a scalp scraping and KOH preparation can help differentiate kerion from secondary bacterial infection.

Kerions are treated the same as tinea capitis, with systemic antifungal agents for 6 to 8 weeks. If bacterial superinfection exists, an antibiotic is added. Antibiotic options include oral cephalaxin, dicloxacillin, or clindamycin. Clindamycin is recommended when community-acquired MRSA is a concern. Surgical drainage of kerions is not helpful and should be avoided.

**Tinea Pedis**

Tinea pedis, commonly referred to as *athlete’s foot*, presents with scaling, maceration, vesiculation, and fissuring between the toes and on the plantar surface of the foot. Common etiologies include *Trichophyton rubrum*, *Trichophyton interdigitale*, and *Epidermophyton floccosum*. Secondary bacterial infection may occur. The vesicular pustular form of tinea pedis should be considered when vesicles and pustules on the instep are noted. Interdigital lesions may cause minimal symptoms and serve as a portal of entry for bacterial cellulitis. The differential diagnosis includes contact dermatitis and dyshidrotic eczema. A KOH preparation is helpful to differentiate between these processes. Treatment options include topical antifungal agents, such as terbinafine twice daily for 2 to 4 weeks; miconazole cream, powder, or spray twice daily for 2 to 4 weeks; and clotrimazole cream, solution, or lotion twice daily for 2 to 4 weeks. For severe disease or if topical treatment has failed, systemic therapy may be instituted with terbinafine for 2 weeks, fluconazole weekly for 2 to 4 weeks, or griseofulvin daily for 2 weeks.

**Tinea Versicolor**

Tinea versicolor, or pityriasis versicolor, is a superficial fungal infection caused by genus *Malassezia*. Superficial hypopigmented or hyperpigmented patches occur mainly on the chest and trunk but may extend to the head and limbs. As the name implies, lesions can be a variety of colors, including pink, tan, and white. The disease may be associated with pruritus. On physical examination, a fine subtle scale is noted that may appear hypopigmented (Fig. 110.24). Pale yellow or orange fluorescence under Wood’s light may be seen. The differential diagnosis includes vitiligo and seborrheic dermatitis. A KOH preparation reveals short hyphae mixed with spores (“chopped spaghetti and meatballs”).

Tinea versicolor may be treated with topical antifungal agents, such as 2.5% selenium sulfide shampoo, imidazole creams, and ketoconazole cream or foam. Systemic therapy may be indicated, such as oral ketoconazole. Recurrence is common. Pigmentation may not return to normal for months.

**Tinea Unguium (Onychomycosis)**

Tinea unguium may be caused by dermatophytes, candida, or other fungal species. Paronychia or untreated tinea pedis may be predisposing factors. Onychomycosis presents with toenails or fingernails that are thickened, opaque, cracked, or destroyed. Subungual debris is present, and the nail may contain yellowish longitudinal streaks (Fig. 110.25). The nail of the great toe is most...
Effects. Treatment failures or relapses are common, and they may be attributed to poor patient compliance, low bioavailability, lack of drug penetration into the nail, drug resistance, and drug interactions. Additional therapies may include surgical removal of the nail, photodynamic therapy, or laser therapy.

Candidiasis

Infection by *Candida albicans* may occur in patients of all ages. Many conditions predispose to infection, including diabetes mellitus, HIV infection, pregnancy, obesity, smoking, malnutrition, malignancy, or treatment with corticosteroids, antibiotics, or immunosuppressive agents.

Oral Candidiasis. Oral candidiasis (“thrush”) is the most common clinical expressions of *Candida* infection. It is common in newborns, elder persons, immunosuppressed individuals, or persons wearing dentures. Oral candidiasis is common in newborns, with one-third being affected by the first week of life. It appears as patches of white or gray friable material covering an erythematous base on the buccal mucosa, gingiva, tongue, palate, or tonsils. Fissures or crust at the corners of the mouth may be present. The differential diagnosis of oral candidiasis includes lichen planus (which unlike *C. albicans* is not easily scraped off), or hairy leukoplakia. Oral mucous membrane infection with *C. albicans* is an AIDS-defining illness. If the patient does not use dentures and has not taken antibiotics recently, underlying immunosuppression should be considered.

Treatment of oral candidiasis may be undertaken with topical antifungal agents, such as clotrimazole troches five times daily, or oral nystatin suspension four times daily, or nystatin pastilles four times daily. Treatment is continued for 5 to 7 days after the lesions disappear. For esophageal candidiasis, systemic antifungal therapy is always required. Oral fluconazole, IV fluconazole, or amphotericin B are options.

Cutaneous Candidiasis. Cutaneous candidiasis favors the moisture and maceration of the intertriginous areas—the interdigital web spaces, groin, axilla, and inframammary folds. Lesions appear as moist, bright red macules rimmed with a collarate of scale, with small satellite papules or pustules are just peripheral to the main body of the rash (Fig. 110.26). These satellite lesions are typical indicators of a *Candida* infection. Intertriginous lesions are prone to bacterial superinfection.

The differential diagnosis of cutaneous candidiasis includes contact dermatitis, tinea cruris, intertrigo, herpes simplex such as
Scabies, the human itch mite, from the Latin word scabere, to scratch, is a human skin infestation caused by the penetration of the obligate human parasitic mite Sarcoptes scabiei-var hominis into the epidermis. It occurs more commonly in winter months. It is transmitted mostly through close personal contacts. It may also be spread by exposure to fomites, because the scabies mite can live off the human skin for 3 days. A KOH preparation of a specimen taken from a pustule and roof of the lesion will reveal hyphae and pseudohyphae.

Scabies presents with intense pruritus and rash, which usually develop after 1 to 8 weeks following exposure. The pruritus is typically worst at night. Clinical findings include small (<5 mm) papules or pustules and small raised or flattened burrows. Classically scabies affects several skin sites, and they are commonly distributed between the digital webs, sides of the fingers, volar aspects of the wrists and lateral palms, trunk, elbows, axillae, scrotum, penis, and the areola in women (Figs. 110.27 and 110.28). Scabies in infants and young children often may present with generalized involvement of the skin, including the face, scalp, palms, and soles. In infants, the most common presenting lesions are papules and vesicopustules.

In crusted scabies (previously known as Norwegian scabies), hyperkeratotic plaques develop diffusely, often on the palmar and plantar regions, with thickening and dystrophy of the toenails and fingernails. Typically with crusted scabies, a host may harbor over a million mites. Individuals with human immunodeficiency virus infection, elders, and patients with medication-induced immunosuppression are at risk of developing crusted scabies.

Scabies is a clinical diagnosis and is based primarily on the history and examination. The definitive diagnosis is made by the microscopic identification of the scabies mites, eggs, or fecal pellets (Scybala). There are various techniques for specimen collection, including lesion scraping, or skin biopsy.24 Because these techniques may be impractical in the ED, treatment should be instituted based on a clinical suspicion of the diagnosis of scabies.24

The differential diagnosis of scabies should include pityriasis rosea, papular urticaria, secondary syphilis, folliculitis, contact dermatitis, atopic dermatitis, seborrhea, dermatitis herpetiformis, lichen planus, and psoriasis.

The first line treatment of scabies is topical permethrin 5% cream (Elimite).25 Permethrin cream should be applied from the neck down, covering all areas of the body including under the nails, in the umbilicus, around the nipples, and genitals. Face and scalp should be treated in affected infants and young children. Preferably, it should be applied prior to bedtime, left on overnight, and then washed off 8 to 12 hours later. It is vital to treat not only the patient but family members and close contacts as well. A second treatment should be administered in 1 to 2 weeks. Alternative therapy may include single dose of ivermectin 200 µg/kg by mouth, or topical crotamiton cream. For heavily infested and or immunocompromised patients, it is recommended that ivermectin be given once a week for 2 to 3 weeks. One recent study demonstrated the efficacy of empirical therapy with a single dose of ivermectin among homeless persons with pruritus. Lindane, a previously used agent, has fallen out of favor due to potential neurotoxicity and resistance. Equally important in the treatment is the decontamination of the clothing, bed linens, and towels by washing them in hot water and hot machine drying. Items that cannot be washed and or dry-cleaned can be decontaminated by sealing the items in an airtight container for at least 72 hours.
Pediculosis

Pediculosis may affect the scalp hair (pediculosis capitis, caused by the mite Pediculus humanus capitis), body (pediculosis corporis, caused by Pediculus humanus corporis), or genitalia (pubic lice, caused by Phthirius pubis). Infestation is typically associated with significant pruritus. Lesions may be erythematous macules, papules, or wheals.

Pediculosis capitis is the most common form of lice infestation in the United States and is frequently seen in children 3 to 12 years old. An estimated 10% to 40% of school children in the United States have been infected with pediculosis capitis. It can be transmitted by sharing hair brushes, combs, and hats, and through contact with infested furniture, clothing, and linens. Hygiene and hair length are unrelated to infection. Incidence is greatest during autumn. Pediculosis capitis is less common among African American patients. Scalp, occipital, and postauricular pruritus are common in patients with pediculosis capitis. Neck and auricular erythema, papules, vesicles, and lymphadenopathy may be seen.

Pediculosis corporis can present with intense pruritus and erythematous macules or wheals. Pediculosis corporis typically occurs in patients with poor hygiene or living in crowded conditions.

Pediculosis pubic (“crabs”) is a sexually transmitted disease and is most commonly seen among young adults. Other concurrent sexually transmitted diseases should be considered and ruled out.

The differential diagnosis includes conditions, such as tinea capitis, seborrheic dermatitis, atopic dermatitis, eczema, scabies, folliculitis, and contact dermatitis.

The diagnosis of pediculosis is made by identification of lice or nits on the hair shaft (Fig. 110.29). Nits, which appear as white dots or grains, are more easily identified than the actual louse. Nits fluoresce with the Wood’s lamp. Examination with a louse comb improves the diagnostic accuracy and is faster than direct visualization.

Therapy for pediculosis should be initiated with a pediculicide, such as permethrin 1% (Nix, Lyclear), which is effective in 90% of cases. Permethrin should be applied to the dry scalp and hair and remain for 10 minutes. Treatment should be repeated in 1 week to kill any newly hatched lice. Spinosad 0.9% suspension (Natroba) is a new agent with demonstrated pediculicidal efficacy. Spinosad 0.9% is approved for use in patients older than 4 years old and is also effective against permethrin-resistant populations of lice. Spinosad is ovicidal, killing both eggs (nits) and lice; thus extensive nit combing is not necessary. However, the cost may be prohibitive. Oral ivermectin (Stromectol, Mectizan) has demonstrated pediculicidal efficacy. Topical ivermectin lotion has also demonstrated safety and efficacy. Other treatments may be considered, including malathion, aldbendazole or thiabendazole, benzyl alcohol lotion (Ulefsia), or levamisole (Ergamisol). Lindane, an older therapy, should be reserved for unusual cases of resistance to first line agents, because of neurotoxicity and poor pediculicidal activity. Over the counter products have variable success rates, in part due to resistance. Nits should be removed with a special fine-toothed comb. The environment should also be treated. Hats, hair brushes and combs, and linens as well as clothing should be treated. Items should be boiled or washed and dried at high temperatures. Floors and furniture should be vacuumed. Fumigation is not necessary. Family members should be examined and treated if infested. Sexual partners of patients with pediculosis pubis should be treated. The American Academy of Pediatrics recommends that children do not miss school because of head lice.

Bed Bugs

Bed bugs (Cimex lectularius) appear brown, approximately 5 to 6 mm in length. Bed bugs may be vectors for many fungi, viruses, and bacteria, including MRSA and vancomycin-resistant Enterococcus faecium, although human illness from bed bugs as carriers has not been documented. Bed bugs are found not only in linens, but on furniture, luggage, and in walls, baseboards, and buildings. They often feed on humans at night with a painless bite.

Clinical presentation may appear as erythematous welts, macules, papules, urticaria, purpura, vesicles, or bullae, with intense pruritus. The distribution is often over uncovered areas, such as arms, legs, and shoulders. Lesions resolve spontaneously in 1 to 2 weeks. Symptomatic treatment should be undertaken with antihistamines and topical corticosteroids. A patient with a scaly, persistent pruritic eruption should be treated with permethrin 5% cream, ivermectin, or crotamiton. Eradication from the environment is challenging, due in part to increasing resistance to insecticides. Eradication methods may include insecticides, heat, steam, freezing, or vacuuming. The hazards of widespread insecticide use, including potential for malignancy or CNS adverse effects, have created a dilemma of eradication.

ALLERGIC REACTIONS

An in depth discussion of systemic allergic reactions and anaphylaxis can be found in Chapter 109.

Contact Dermatitis

Contact dermatitis is an inflammatory reaction of the skin to a chemical, physical, or biologic agent, which acts as an irritant or allergic sensitizet. Allergic contact dermatitis is a form of delayed hypersensitivity mediated by lymphocytes sensitized by the contact of the allergen to the skin. It is less common than irritant contact dermatitis. Caustics, industrial solvents, and detergents are common causes of irritant dermatitis. Clothing, jewelry, soaps, cosmetics, latex, plants, and medications contain allergens that commonly cause allergic contact dermatitis. The most common allergens include rubber compounds; plants of the Toxicodendron species, including poison ivy, oak, and sumac; nickel, often used in jewelry alloys; paraphenylenediamine, an ingredient in hair dyes and industrial chemicals; and ethylenediamine, a stabilizer in topical medications.

The primary lesions of contact dermatitis are papules, vesicles, and bullae on an erythematous base. Streaky, linear, intensely pruritic lesions are characteristic. A pattern in the region in contact with the allergen is typical (Fig. 110.30). Eruptions associated with contact dermatitis can appear as soon as several hours after the exposure or may be delayed for days.
Urticaria may occur in isolation or as part of a systemic anaphylactic reaction. The following discussion pertains to urticaria occurring in the absence of systemic symptoms. Anaphylactic reactions and angioedema are discussed in Chapter 109. Approximately 15% to 20% of the population experiences urticaria during their lifetime. Acute urticaria is seen in both sexes and is more likely to have an allergic cause. Chronic urticaria is more common in women in their 40s and 50s. Half of all patients with chronic urticaria have the disease for 5 years and one-fourth for 20 years.

Various mediators, including histamine, bradykinin, kallikrein, and acetylcholine, are thought to play a role in urticaria production. Urticaria may be initiated by immunologic or nonimmunologic mechanisms. Nonimmunologic urticaria may be produced by degranulation of mast cells, which may be caused by a number of foods and drugs, including aspirin and narcotics.

Almost any medication may produce urticaria, although penicillin and aspirin are the most common. Traces of penicillin may be present in dairy products, as well as in medications. The mechanism of production of urticaria by aspirin is unknown but is probably nonimmunologic, and the effects of aspirin may persist for a number of weeks after ingestion. The role of medications in the production of urticaria is discussed in the section on drug reactions. Substances that can cause urticaria by contact with the skin include foods, textiles, animal dander and saliva, plants, topical medications, chemicals, and cosmetics. A variety of food allergies, such as seafood, tree nuts, peanuts, and eggs, may result in urticaria. In addition, foods such as lobster and strawberries can release histamine through a nonimmunologic mechanism.

Infection is a common cause of urticaria. Viral infections that produce urticaria include rhinovirus, rotavirus, hepatitis, mononucleosis, and coxsackievirus infections. Occult infections with *Candida*, the dermatophytes, bacteria, viruses, and parasites may also cause urticaria.

Inhalation of pollens, mold, animal dander, dust, plant products, and aerosols may produce urticaria. Respiratory symptoms may accompany the dermatosis, and a seasonal pattern of occurrence may be present. Stings and bites of insects, arthropods, and various marine animals may also produce an urticarial eruption.

On occasion, patients with systemic lupus erythematosus, lymphoma, carcinoma, hyperthyroidism, rheumatic fever, and juvenile rheumatoid arthritis develop an urticarial eruption.

A number of physical agents produce urticaria. Dermatogramphism is present when firm stroking of the skin produces an urticarial wheal within 30 minutes and is the most common form of physical urticaria. Pressure urticaria is distinct from dermatogramphism in that the onset of urticaria is delayed by 4 to 8 hours after the application of physical pressure.

Cold urticaria may be either familial or, more commonly, acquired. Cold urticaria may also be associated with underlying illness, such as cryoglobulinemia, cryofibrinogenemia, syphilis, and connective tissue disease. Nonsedating antihistamines, such as rupatadine, help suppress primary cold urticaria.37 Antihistamines taken 30 to 60 minutes before cold exposure may be helpful. Cholinergic urticaria is induced by exercise, heat, or emotional stress. It may be associated with pruritus, nausea, abdominal pain, and headache. The lesions of cholinergic urticaria are wheals 1 to 3 mm in diameter surrounded by extensive erythematous flares and, occasionally, satellite wheals. Nonsedating antihistamines are generally used to treat cholinergic urticaria.

Heat is a rare cause of hives. Solar urticaria, also uncommon, is confined to sun-exposed areas of skin and clears rapidly when the light stimulus is removed. Extensive sun exposure may cause wheezing, dizziness, and syncope in a susceptible individual. Sunscreens have not been proven to be effective for the prevention of solar urticaria. Phototherapy may be used to induce tolerance.

Urticaria appears as edematous plaques with pale centers and red borders and is easily recognizable (Fig. 110.31). Individual hives are typically transient, lasting less than 24 hours, although
new lesions may continuously develop, which represents localized dermal edema produced by transvascular fluid extravasation.

The differential diagnosis of urticaria includes drug eruption, exanthems, erythema multiforme, erythema marginatum, and juvenile rheumatoid arthritis.

Treatment of urticaria involves the removal of the inciting factor, when applicable, and the administration of antihistamines or other antipruritics. Hydroxyzine (Atarax, Vistaril) is usually effective in providing symptomatic relief. For chronic urticaria, long-term therapy with antihistamines may be needed. Nonselecting antihistamines are preferred. Cetirizine, fexofenadine, or loratadine can be used. A single dose of an H2 blocker may be added.

Steroids may be a useful adjunctive therapy. Patients with moderate or severe urticaria may benefit from prednisone or dexamethasone. Patients with recurrent urticaria may benefit from longer courses of oral steroids (14 to 21 days with a taper). Chronic administration of steroids is not recommended.

Patients with chronic urticaria may be treated with a prescription for a combination of an H1 and H2 antihistamine. Strong evidence supporting addition of an H2 blocker is lacking. For patients with recurrent urticaria, a prescription of injectable epinephrine may be indicated.

Poison Ivy

Toxicodendron species often result in vesicular or bullous eruptions. Oozing, crusting, scaling, and fissuring may be found along with lichenification in chronic lesions. The distribution of the eruption depends on the specific contact and may be localized, asymmetric linear, or unilateral (Fig. 110.32). Mucous membranes are usually spared unless they are directly exposed to the inciting agent. Sensitization to poison ivy results in sensitization to other plants in this family, such as cashew, mango, lacquer, and ginkgo trees.

In addition to the aforementioned treatment regimen for contact dermatitis, a course of systemic corticosteroids may be indicated to treat Toxicodendron-associated dermatitis. A tapering dose of prednisone for 21 to 30 days may be indicated to prevent rebound of the disease. Patients should be counseled to wash all clothes or items that might have contacted the plant because the irritant plant oil can persist. Once the offending agent is reliably removed from the skin and clothes, ongoing outbreak is attributable to the initial contact, not spread from the serous fluid from the bullae. The patient is not contagious to others unless there is direct contact with the plant oil in people who are sensitized.

DRUG REACTIONS

Reactions to medications are common and are estimated to occur in 1% to 5% of patients. Cutaneous reactions are the most common type of reaction. Many medications have the potential to produce a drug reaction. Patients at higher risk of drug reactions include those with immunodeficiency, certain infections, and genetic predisposition. The most common eruptions are a morbilliform rash (Fig. 110.33), urticaria, or fixed drug eruption. More severe reactions may include vasculitis, erythema nodosum, angioedema, anaphylaxis, Stevens-Johnson syndrome, toxic epidermal necrolysis, blistering dermatoses, drug-induced lupus, lichenoid drug eruptions, psoriasiform drug eruptions, drug-induced neutrophilic dermatoses (i.e., Sweet’s syndrome, erythema nodosum, and pyoderma gangrenosum), and cutaneous lymphoma-like drug reactions.

Drug reactions often appear within 4 to 21 days after the drug is taken. Skin lesions may appear after a drug has been discontinued and may worsen if the drug or its metabolites persist in the system. Special note should be made of penicillin, because it is a common cause of drug reaction. Serum sickness and urticaria are common manifestations of penicillin allergy. Geriatric patients, patients with HIV infection, atopic patients, and those with a history of hay fever, asthma, or eczema are at increased risk.

A variety of skin reactions are associated with drug reactions. Exanthematous drug eruptions, including maculopapular and morbilliform drug eruption, are the most common type of cutaneous manifestation and account for over 80% of reactions. Clinical presentation is typically a widespread symmetric eruption of pink or red macules and papules which may become confluent. Severe cases may progress to exfoliative dermatitis.

Other presentations may include urticarial, eczematous drug rash, vasculitis, photosensitive drug reactions, or fixed drug eruption. Fixed drug eruptions appear and recur at the same anatomic site after repeated exposure to the same drug. The lesions are usually sharply margined and round or oval. They may be pigmented, erythematous, or violaceous. Pruritus may be prominent.

Treatment of drug eruptions begins with discontinuation of the inciting agent. Most cutaneous drug reactions fade within 1 week of discontinuation. Antihistamines, H1-antagonists, and topical or systemic steroids may be indicated.
Severe reactions, such as toxic epidermal necrolysis, Stevens-Johnson syndrome, and hypersensitivity reactions warrant hospitalization.

**INFLAMMATORY CONDITIONS**

**Atopic Dermatitis**

Atopic dermatitis is a common dermatologic condition often referred to as *eczema* or *chronic dermatitis*. Atopic dermatitis is the cutaneous manifestation of an atopic state, and although it is not an allergic disorder, it is associated with allergic diseases, such as asthma and allergic rhinitis. Patients with atopic dermatitis are known to have abnormalities of both humoral and cell-mediated immunity. The exact mechanism is unclear, but eosinophil, mast cell, and lymphocyte activation triggered by increased production of cytokines is involved. The disease may occur. The eruption is usually asymptomatic, although pruritus may be present. The differential diagnosis includes tinea corporis, guttate psoriasis, lichen planus, drug eruption, Lyme disease, and secondary syphilis.

Atopic dermatitis is an inflammatory skin condition. Diagnostic criteria include itchy skin plus three or more of the following: history of flexural involvement, generalized dry skin in the past year, history of asthma or hay fever, onset of rash before 2 years old, and flexural dermatitis.

Skin lesions generally appear as inflammatory thickened, papular, or papulovesicular lesions. The skin is typically dry and may be scaly, but in the acute phase, it may also be vesicular, weeping, or oozing. In the chronic stage, lesions are thickened and lichenified.

The distribution of lesions varies with the age of the patient. In infants, inflammatory exudative plaques are seen on the cheeks, on the extensor surfaces, and in the diaper area. Older children and adults have lesions in the antecubital and popliteal flexion areas, neck, face, and upper chest. Infantile atopic dermatitis usually begins in the fourth to sixth month of life and improves by the third to fifth year of life. The childhood form occurs between 3 and 6 years old and resolves spontaneously or continues into the adult form.

Intense pruritus is a hallmark of atopic dermatitis. During flares, patients may present with complaints of intense itching and failure of routine treatments to control their symptoms. Patients may also present with secondary infections. The itching may be focal or generalized, is worse during the winter, and is triggered by increased body temperature and emotional stress. It may be particularly annoying at night. Excoriations may be prominent, and secondary bacterial infection of excoriated lesions is common. Repeated scratching and rubbing produce lichenification, a condition of hyperpigmentation, thickening of the skin, and accentuation of skin furrows. Lichenification is a common feature of chronic atopic dermatitis.

Treatment should be aimed at control of inflammation, dryness, and itching. Management includes a careful review of daily skin care with patients or caregivers. General recommendations for all patients include avoidance of nonspecific skin irritants, wool, nonessential toiletries, and detergents and use of cotton clothing as much as possible.

Topical corticosteroids are the cornerstone of therapy and are often best prescribed in ointment form. Approximately 80% of patients have improvement of symptoms with topical steroid treatment. When the dermatitis is severe, the application of a fluorinated corticosteroid ointment such as half-strength betamethasone valerate is recommended to affected areas three times a day. Fluorinated corticosteroids should not be used on the face, because they can produce cutaneous atrophy. Milder corticosteroid preparations, such as 0.025% triamcinolone ointment, may be used on the face and intertriginous areas. Patients with extremely severe disease may require systemic steroids. Ultraviolet B treatment is moderately effective. Cyclosporine and other immunosuppressant agents are being used with some promising benefit. Further studies are needed to determine ideal dosing and safety profiles for these agents.

Skin dryness is treated with lubricating ointments such as Vaseline or 10% urea in Eucerin cream (not lotion). Treatment of exudative areas includes the application of wet dressings, which are useful for their moisturizing, antiinflammatory, and antipruritic actions. Two or three layers of gauze soaked in Burow’s solution should be applied for 15 to 20 minutes four times a day for exudative lesions. Antihistamines may be helpful in reducing the pruritus and are also useful for their sedative and soporific effects, although there is no convincing evidence that H1 antihistamines decrease itching in patients with atopic eczema.

Inpatient admission is a consideration for those patients who have generalized erythema and exfoliation (erythroderma) or intractable itching in that skin breakdown and severe secondary bacterial or viral skin infections may occur.

Patients with atopic dermatitis are susceptible to infection and colonization by a variety of organisms because of their defective skin barrier functions and local skin immunodeficiency. Widespread disseminated viral infections, such as eczema molluscum, eczema vaccinatum, and eczema herpeticum, and recurrent staphylococcal pustulosis are especially concerning.

**Pityriasis Rosea**

Pityriasis rosea is a mild skin eruption predominantly found in children and young adults. The etiology is unknown, although viral, bacterial, and fungal etiologies have been implicated. Ages 10 to 35 years are commonly affected. Clinical presentation includes multiple pink or pigmented oval papules or plaques 1 to 2 cm in diameter on the trunk and proximal extremities. A history may reveal an initial larger patch (“herald patch”) that precedes the widespread eruption (Figs. 110.34 and 110.35). Mild scaling may be present. The lesions are parallel to the ribs, forming a Christmas tree–like distribution on the trunk and extremities.

Oral lesions are rare. In children, papular or vesicular variants of the disease may occur. The eruption is usually asymptomatic, although pruritus may be present. The differential diagnosis includes tinea corporis, guttate psoriasis, lichen planus, drug eruption, Lyme disease, and secondary syphilis.

Pityriasis rosea is self-limited, resolving in 8 to 12 weeks. Recurrences are rare. Treatment should include supportive care, including alleviation of pruritus. Topical zinc oxide and calamine lotion are useful for pruritus. If the disease is severe or widespread (e.g., vesicular PR), topical or oral steroids may be used. No restriction of activity or isolation is indicated.

**Fig. 110.34.** Herald patch of pityriasis rosea.
**Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)**

Kawasaki disease (mucocutaneous lymph node syndrome) is one of the most common vasculitides of childhood. It is seen in infants and young children. The peak age is between 1 and 2 years old. The disease is very uncommon in children older than 14 years old or in adults. It is more common in boys. Although cases of Kawasaki disease have been reported in children of all ethnic origins, the highest incidence is among children of Asian descent. The disease typically occurs in winter and spring and is usually self-limiting, resolving spontaneously without treatment within 2 to 4 weeks. However, 15% to 20% of cases will have complications, such as damage to coronary arteries, leading to myocardial infarction and heart failure.

Clinical features are characterized by three phases. The acute febrile period (phase I) is manifested by the abrupt onset of fever, lasting approximately 12 days. During phase I, cutaneous findings include erythematous lesions and on the palms and soles. Within 2 days, the blotchy, erythematous, macular lesions spread to the extremities and trunk. Nonexudative injected conjunctivae, seen in approximately 90% of patients, may be present for 1 to 3 weeks. Diffuse oropharyngeal erythema with “strawberry” tongue is often present. Symptoms of diarrhea, arthritis, and photophobia may be present. In the subacute phase (phase II), desquamation, thrombocytosis, arthritis, arthralgias, and carditis may be present. This phase may last 30 days. There is a high risk for sudden death during this phase of the illness if it has gone untreated. During the convalescent phase (phase III), which occurs within 8 to 10 weeks after the onset of the illness, most signs of the illness have resolved. Coronary aneurysms present in 25% of cases and may be diagnosed by echocardiography or coronary angiography.

For epidemiologic surveillance, the Centers for Disease Control and Prevention (CDC) defines a case of Kawasaki disease as illness in a patient with fever of 5 or more days duration, and the presence of at least four of the following five clinical signs:

- Rash
- Cervical lymphadenopathy (at least 1.5 cm in diameter)
- Bilateral conjunctival injection
- Oral mucosal changes
- Peripheral extremity changes.

The diagnosis is typically made based on clinical findings. Laboratory tests that support the diagnosis include elevated liver function tests, leukocytosis, thrombocytosis and an elevated C-reactive protein (CRP). The ESR is elevated during phase II and returns to normal in phase III. Pyuria may be seen on urinalysis.

**Electrocardiography** (ECG) may show PR and QT prolongation or acute ST/T wave changes.

Management of Kawasaki disease includes hospital admission, high dose intravenous immune globulin (IVIG) (2 g/kg single dose) therapy, and aspirin therapy (80 to 100 mg/kg per day). Treatment with IVIG within the first 10 days of illness reduces the incidence of coronary artery aneurysms fivefold compared with children not treated with IVIG. Early cardiology evaluation is important to identify and treat possible coronary artery involvement.

An in depth discussion of Kawasaki disease can be found in Chapter 170.

**Erythema Multiforme**

Erythema multiforme is considered to be a hypersensitivity reaction, and it may be caused by a drug reaction; HSV infection and other viral infections, especially hepatitis and influenza A; fungal diseases, such as dermatophytosis, histoplasmosis, and coccidioidomycosis; and bacterial infections, especially streptococcal infections and tuberculosis. Various collagen vascular disorders have been known to precipitate erythema multiforme, including rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, and periarteritis nodosa. Pregnancy and various malignant neoplasms have also been associated with erythema multiforme. The etiology is unknown in approximately 50% of cases. Differential diagnosis includes urticaria, scalded skin syndrome, pemphigus, and pemphigoid and viral exanthems.

Erythema multiforme is an acute, usually self-limited disease. It is characterized by skin lesions that are erythematous or violaceous macules, papules, vesicles, or bullae. Their distribution is often symmetric, most commonly involving the soles and palms, the backs of the hands or feet, and the extensor surfaces of the extremities. The presence of lesions of the palms and soles is particularly characteristic. The target lesion with three zones of color is the hallmark of erythema multiforme (Fig. 110.36). It is a central, dark papule or vesicle that is surrounded by a pale zone, a halo of erythema, and is commonly found on the hands or wrists.

Treatment begins with treatment of the underlying cause. Mild forms with no systemic symptoms, lesions limited to extremities,
and no mucous membrane involvement typically resolve spontaneously in 2 or 3 weeks. Patients with lesions on the trunk and patients who are immunocompromised, especially those with multiple lesions, require a course of systemic steroids for 14 to 21 days with a taper and urgent dermatology referral. Patients with mucous membrane involvement, systemic symptoms, or vesicle formation raise concern for Stevens-Johnson syndrome.

**Toxic Epidermal Necrolysis**

Stevens-Johnson syndrome and toxic epidermal necrolysis are considered a continuous spectrum of the same disease, an immune-complex–mediated hypersensitivity reaction. Stevens-Johnson syndrome is considered a minor form of toxic epidermal necrolysis with less than 10% body surface area (BSA) involved. Toxic epidermal necrolysis includes patients with more than 30% BSA involved. There is overlap with patients with 10% to 30% BSA involved. The main feature of non–staphylococcal-induced toxic epidermal necrolysis, or Lyell’s disease, is the separation of large sheets of epidermis from underlying dermis. Toxic epidermal necrolysis may be caused by medications, infection, malignancy, or idiopathic (30% to 50% of cases). Medications that can cause toxic epidermal necrolysis include sulfa drugs, nonsteroidal antiinflammatory drugs (NSAIDs), penicillin, aspirin, barbiturates, phenytoin, carbamazepine, or allopurinol.

Mortality may be up to 30% with toxic epidermal necrolysis. Risk factors for poor prognosis include age older than 40 years old, underlying malignancy, heart rate more than 120, initial percentage of epidermal detachment more than 10%, BUN level more than 10 mmol/L, serum glucose level more than 14 mmol/L (or 252 mg/dL), and bicarbonate level less than 20 mmol/L.

Toxic epidermal necrolysis commonly begins with prodromal symptoms, such as fever, malaise, rhinitis, sore throat, and myalgias. These are followed by the abrupt development of a macular rash that may appear as target lesions. The extremities are commonly involved, although any area may be affected. The exanthem becomes confluent, and dermal-epidermal dissociation ensues; Nikolsky’s sign (denudation with shear stress) is present, and the skin is commonly painful to the touch (Fig. 110.37). Mucous membrane involvement may occur with erythema, blistering, sloughing, or necrosis (Fig. 110.38). Involvement of the conjunctivae and cornea may lead to permanent scarring and blindness. Systemic involvement may occur, with renal, gastrointestinal, or respiratory tract lesions, resulting in hematuria, diarrhea, bronchitis, or pneumonia. Morbidity and mortality are often related to infection and dehydration.

The treatment of Stevens-Johnson syndrome and toxic epidermal necrolysis includes discontinuation of the offending agent and supportive care, including hydration, prevention of secondary infection, and expert wound management. This is usually best accomplished in a center with burn care expertise. Systemic administration of corticosteroids is controversial. They have little effect on the disease and may mask signs of impending sepsis. High-dose IVIG may be administered to patients with severe toxic epidermal necrolysis or Stevens-Johnson syndrome. Plasmapheresis is considered in consultation with a specialist.

An in depth discussion of Stevens-Johnson syndrome and toxic epidermal necrolysis can be found in Chapter 129.

**Erythema Nodosum**

Erythema nodosum is an inflammatory reaction of the dermis and adipose tissue that presents with painful erythematous or violaceous subcutaneous nodules. These painful nodules occur most commonly over the anterior tibia but may also be seen on the arms or body (Fig. 110.39). Fever and arthralgia of the ankles and knees may precede the rash. As the lesions evolve, they may turn yellow-purple and resemble bruises. Women are affected three times more often than men, with the highest incidence in the third to fifth decades of life. Unless lesions quickly resolve, a search for underlying conditions should be undertaken.

A number of diseases are associated with erythema nodosum; these include drug reactions, sarcoidosis, coccidioidomycosis,
Pemphigus Vulgaris

Pemphigus vulgaris is an uncommon but important dermatologic disorder. The mortality rate before the use of steroids was approximately 95%. The current mortality rate is 10% to 15%, with appropriate treatment. Pemphigus is a bullous disease, affecting both sexes equally, and is most common in patients 40 to 60 years old. The disease is mostly prevalent in people of Jewish, Mediterranean, or south Asian descent.

The typical skin lesions are small, flaccid bullae that break easily, forming superficial erosions and crusted ulcerations. Any area of the body may be involved. Nikolsky’s sign is present and characteristic of the disease. Nikolsky’s sign is positive when gentle rubbing of the skin produces exfoliation of the outermost layer, forming a blister or bullae.

Many patients also have oral lesions (50% to 60%). The oral lesions typically antedate the cutaneous lesions by several months. The most common site is in the mouth, especially the gums and vermilion borders of the lips. Oral lesions are bullous but commonly break, leaving painful, denuded areas of superficial ulceration.

Pain control and local wound care are essential components of therapy. Once the diagnosis is made, treatment with oral glucocorticoids in initial doses of 100 to 300 mg of prednisone, or an equivalent drug, should be instituted in conjunction with a dermatologist. Other immunosuppressant drugs may also be used. Morbidity and mortality may ensue, related to an uncontrolled spread of the disease, secondary infection, dehydration, side effects of steroid therapy, and thromboembolism.

Fig. 110.40. Lichen planus. (Courtesy Centers for Disease Control and Prevention [CDC] Public Health Image Library, Susan Lindsley.)

that most commonly produce cutaneous extension are lympho-dermatologist for biopsy.

Squamous cell carcinoma is the second most common skin cancer in the United States. It is more common in men than women. The risk of developing squamous cell carcinoma of the skin is increased with advancing age and sun exposure. Squamous cell carcinomas are typically found in sun-exposed areas, most commonly on the head and neck. The appearance is typically an irregular growth with erythema, induration, inflammation, crusting, or oozing. Suspicious lesions should be referred to a dermatologist for biopsy.

Melanoma is less common, and accounts for only 4% to 5% of skin cancers. However, it is responsible for most deaths from cutaneous malignancies. Risk factors include fair skin, dysplastic nevi, multiple (>50) nevi, prior history of melanoma, family history of melanoma, immunocompromised state, and xeroderma pigmentosum. Melanoma tends to appear more often on lower extremities in women and on the head, neck, and trunk in men, and it may occur in any area of the skin. The typical appearance is an asymmetric lesion with irregular pigmentation, border, and texture, and diameter greater than 6 mm or increasing in size. Suspicious lesions should be referred to a dermatologist for biopsy.

Kaposi sarcoma appears more often in men having sex with men than in other risk groups. Clinically, it presents with painless, raised, brown-black or purple papules and nodules that do not blanch. Common sites are the face, chest, genitals, and oral cavity, but widespread dissemination involving internal organs may occur. Because cutaneous Kaposi sarcoma is not generally associated with morbidity or mortality, therapy is indicated only for extensive, painful, or cosmetically disfiguring lesions.

Although the ED does not provide definitive management for cutaneous malignancies, recognition of possible malignant lesions may facilitate prompt and expeditious referral for definitive management. Any lesion with irregular pigmentation, irregular borders or texture, easy bleeding, or recent change in lesion should be referred to a dermatologist.

SKIN CONDITIONS ASSOCIATED WITH SYSTEMIC DISEASE

Systemic illness should be considered with significant generalized dermatologic presentations. Systemic illness should be suspected in patients with systemic symptoms, such as fever, fatigue, weight loss or gain, weakness, immunosuppression, or other generalized symptoms. Systemic illnesses with cutaneous findings may include systemic infections, autoimmune or connective tissue disorders, malignancies, diabetes mellitus, endocrine disorders, and immunodeficiency states (Table 110.4).

Cutaneous lesions most directly indicative of an internal malignant disease arise from the extension of the tumor to the skin or by hematogenous or lymphatic metastasis. The neoplasms that most commonly produce cutaneous extension are lymphomas, leukemias, and carcinomas of the breast, gastrointestinal tract, lung, ovary, prostate, uterus, and bladder. Skin metastases generally signify a poor prognosis.

Pruritus may be a sign of systemic disease, such as cholestasis, renal disease, malignancy, or myeloproliferative disease. Malignancies associated with pruritus include Hodgkin’s disease, leukemia, adenocarcinoma or squamous cell carcinoma of various organs, carcinoid syndrome, multiple myeloma, and polycythemia vera. It may be present years before the underlying malignant disease is identified. It may be intractable and associated with urticaria, erythroderma, excoriations, or lichenification.

**IBD,** Inflammatory bowel disease; **SLE,** systemic lupus erythematosus.
and nonthrombocytopenic forms are differentiated by the results of the patient’s platelet count.

Petechiae are manifestations of intradermal hemorrhage. Petechiae may be associated with thrombocytopenia, allergic reactions, infections, trauma, or malignancy (Fig. 110.42).

**MANAGEMENT**

Treatments for dermatologic conditions should address both definitive treatment for underlying disease states and symptomatic treatment. If causative agents are identified, they should be discontinued or eliminated from the environment. Topical or systemic therapies may be indicated for a variety of conditions.

Vehicles for topical dermatologic preparations may be important in the therapeutic effect. Vehicles include creams (water based emulsion of oil), lotions (water based suspension of powder), ointments (oil based suspension, which improves penetration of the active ingredient), gels (transparent, semi-solid, non-greasy emulsion), foams (helpful for scalp or difficult to reach areas), and pastes (ointment base with powder, stiff consistency). For dry, scaly conditions, emollients such as ointments may be more effective. For moist conditions, a dryer vehicle such as a gel or powder may be preferable. Vehicle components may vary with generic preparations, and it is important to monitor clinical success if generic preparations are prescribed. Communication with the patient about preferences may be important. Patient preference and compliance are closely linked to successful outcomes.

Topical steroids are commonly used to treat inflammatory dermatologic conditions. Topical steroids have several mechanisms of action, including antiinflammatory effects, antiproliferative effects on fibroblasts and collagen, reduction of leukocyte adhesion to capillaries, reduction of capillary wall permeability, reduction of complement components, and histamine antagonism. Adverse effects may include skin atrophy, striae, acneform lesions, pigment changes, telangiectasia, hypothalamic-pituitary axis suppression from systemic absorption, and exacerbation of certain conditions, such as fungal infections and viral infections. Topical steroids should be prescribed in the lowest potency and for the shortest duration that is effective for the individual patient (Table 110.5).

Systemic therapies are appropriate for systemic conditions. Commonly used systemic therapies include oral, IM, or IV

steroids, antipruritic agents, antibiotics, antifungal agents, and antiviral agents.

**DISPOSITION**

Most ED patients with dermatologic complaints can be successfully managed as outpatients. Indications for inpatient hospitalization include systemic disorders with dehydration, disorders of thermoregulation, systemic infection or other systemic disorder requiring inpatient management, inability to care for self, or maintain appropriate oral intake. Dermatologic outpatient follow-up or inpatient consultation may be appropriate.

**KEY CONCEPTS**

- Accurate descriptions of the lesion(s) are essential for accurate diagnosis and management.
- Key steps in diagnosing the unknown rash include an accurate history, physical examination, including lesions and distribution, and appropriate diagnostic tests. Bacterial infections may present as abscess, cellulitis, impetigo, or other cutaneous infections.
- Incision and drainage is adequate therapy for simple abscesses.
- Antibiotics to cover MRSA are appropriate for most skin and soft tissue infections.
- Tinea capitis requires 4 to 8 weeks of systemic antifungal treatment.
- Allergic reactions are common. Identification and removal of exposure to the allergen, and antihistamine treatment are the cornerstones of therapy.
- Newer nonsedating antihistamines are a useful alternative to older sedating ones to control pruritus and histamine-mediated rashes while allowing the patient to remain active.
- Infestations should be diagnosed clinically and treated expeditiously even without definitive proof of the infestation.
- Medication reactions are common and may result from any medication, typically within 4 to 21 days after taking the medication.
- Rashes that are associated with mucosal lesions, blisters, or desquamating skin are often caused by significant soft tissue infections, drug eruptions, or immune disorders.
- Patients with Stevens-Johnson syndrome and toxic epidermal necrolysis require inpatient treatment, preferably in a burn unit.
- Cutaneous signs of systemic disease may include pruritus, urticaria, erythema multiforme, erythema nodosum, pyoderma gangrenosum, and others.
- Physicians should be familiar with one or two topical steroid preparations of low, medium, and high potency and their appropriate therapeutic use.
- Most patients with dermatologic conditions can be appropriately managed with outpatient treatment and follow-up with a dermatologist. Life-threatening conditions at risk for dehydration and infection require inpatient treatment.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
REFERENCES

30. Geha AN: Treatment of scabies. A 16-year-old boy presents with an erythematous swelling of his left forearm. What is the appropriate initial antibiotic? A. Azithromycin B. Clindamycin C. Ceftriaxone D. Linezolid E. Penicillin VK

CHAPTER 110: QUESTIONS & ANSWERS

110.1. Which of the following statements regarding tinea capitis is TRUE?

A. It is contagious.
B. It is not transmitted by household pets.
C. Tinea capitis presents with alopecia with normal underlying scalp.
D. Topical treatment is effective.
E. Treatment should be instituted for 1–2 weeks.

110.2. A 16-year-old boy presents with an erythematous swelling of his left forearm. What is the appropriate initial antibiotic?

A. Azithromycin
B. Clindamycin
C. Ceftriaxone
D. Linezolid
E. Penicillin VK

Answer: A. Clindamycin or trimethoprim-sulfamethoxazole are recommended first line treatment choices. Macrolides and penicillins are often ineffective against MRSA. Linezolid, although effective, is expensive and is not recommended as a first line treatment.

110.3. What is the causative organism of erythema migrans?

A. <i>Borrelia burgdorferi</i> B. <i>Group A Streptococcus</i> C. Methicillin-resistant <i>Staphylococcus aureus</i> D. <i>Neisseria meningitides</i> E. Parvovirus B-19

Answer: A. Borrelia burgdorferi is the causative agent of erythema migrans, or Lyme disease. Treatment should be instituted with doxycycline for 10–21 days, or as alternates, cefuroxime, ceftriaxone, or penicillin G. Group A Streptococcus is the causative organism of scarlet fever. <i>Neisseria meningitides</i> is the causative agent of Meningococcemia. Parvovirus B-19 is the causative agent of erythema infectiosum.
110.4. A 26 year old man presents with an erythematous maculopapular eruption of his torso, palms, and soles. He had a painless lesion on his penis 1 month earlier. What is the treatment of choice?
A. Azithromycin
B. Benzathine penicillin G
C. Ceftriaxone
D. Doxycycline
E. Trimethoprim-sulfamethoxazole

Answer: B. Secondary syphilis is treated with benzathine penicillin G in a dose of 2.4 million units IM.

110.5. A 25 year old female presents with fever, migratory polyarthralgias, and hemorrhagic papules on her fingers and wrists. What is the best treatment?
A. Ceftriaxone
B. Ciprofloxacin
C. Doxycycline
D. Ofloxacin
E. Vancomycin

Answer: A. Treatment of disseminated gonococcal infection is with parenteral ceftriaxones, or ceftizoxime or cefotaxime. Patients allergic to β-lactam antibiotics or those with severe penicillin allergies may be treated with spectinomycin. Ciprofloxacin and ofloxacin are not recommended because of increasing resistance patterns. Hospitalization is recommended for patients with disseminated gonococcal infection.

110.6. Which of the following statements regarding gonococcal dermatitis is TRUE?
A. Gonococci can usually be seen on gram stain from the lesions.
B. It affects primarily men.
C. It occurs in 1% or 2% of patients with gonorrhea.
D. The lesions have a predilection for the knees and elbows.
E. The skin lesions are not tender.

Answer: C. Women are affected primarily. The lesions have a predilection for distal joint skin. The lesions are often multiple and have a predilection for periarticular regions of the distal extremities. The lesions begin as erythematous or hemorrhagic papules that evolve into pustules and vesicles with an erythematous halo. They may be tender and may have a gray necrotic or hemorrhagic center. The organism may be cultured from the cutaneous lesions. Gram stain only occasionally reveals the organisms.

110.7. A 30 year old man presents with headache, nausea and vomiting, myalgias, fever, and a rash of petechiae on the extremities and trunk. Lesions are clustered on the palms and soles. What is the best treatment?
A. Cephalexin.
B. Doxycycline.
C. Erythromycin.
D. Penicillin VK.
E. Trimethoprim-sulfamethoxazole.

Answer: B. Patients with Rocky Mountain Spotted Fever present with headache, nausea and vomiting, myalgias, chills, and fever. The disease may last 3 weeks and may be severe with prominent involvement of the central nervous system, cardiac, pulmonary, gastrointestinal and renal systems, disseminated intravascular coagulation, or shock. The rash begins with erythematous macules that blanch on pressure, appearing first on the wrists and ankles. These macules spread up the extremities and to the trunk and face. They may become petechial or hemorrhagic. Lesions on the palms and soles are particularly characteristic. Doxycycline is the antibiotic of choice. Chloramphenicol may be used for patients allergic to tetracyclines and in children younger than 9 years. Sulfur drugs should be avoided because they may exacerbate the illness. Rickettsiae are routinely resistant to penicillins, cephalosporins, aminoglycosides, and erythromycin.
CHAPTER 111

Blood and Blood Components

Matthew Emery

PRINCIPLES

Background and Importance

The modern blood transfusion era began with identification of the ABO red cell antigen system in the early 1900s. The subsequent discovery that adding citrate enabled the storage of anticoagulated blood led to the establishment of the first blood banks in the United States in the 1930s, and blood banking expanded rapidly after World War II. In subsequent decades, transfusion research focused primarily on critical issues such as developing component therapy, prolonging the storage life of blood products, and reducing the risk of transfusion reactions and transfusion-related infections.

Decisions about which patients would benefit from red cell transfusion were guided by the expert advice of early pioneers such as John Lundy of the Mayo Clinic, who proposed that patients benefited from transfusion when their hemoglobin (Hgb) level was less than 10 g/dL or after a loss of more than 15% of circulating blood volume. These recommendations were not evidence-based, however, and randomized trials reported in the past 2 decades have led to the adoption of more restrictive red cell transfusion guidelines; they also highlighted the need for emergency clinicians to weigh the risks and benefits that come with administration of all blood products carefully.

Anatomy, Physiology, and Pathophysiology

Sound transfusion decision making is informed by a thorough working knowledge of the underlying physiology and pathophysiology, as well as familiarity with the key clinical trials that support up to date, evidence-based guidelines. This knowledge facilitates the effective ordering and interpretation of laboratory tests, delivery of blood products, and management of common and serious complications.

Blood Banking

Red blood cell (RBC) storage methods aim to ensure viability of at least 75% of the cells 24 hours after infusion. Blood collection bags contain an anticoagulant that ensures a shelf life of 35 days and a hematocrit of 70% to 80% for packed RBCs (PRBCs). Additive solutions provide additional nutrients and extend maximum storage to 42 days. Leukoreduced red cell products are now used for more than 95% of patients in the United States.1 Universal prestorage leukoreduction of blood products has been adopted by an increasing number of developed countries, but remains controversial in the United States due to concerns about whether the benefits justify the costs. I recommend the use of prestorage leukoreduced blood products, when available.

A number of biochemical and structural changes have been documented to occur during red cell storage, including loss of deformability, leakage of potassium, irreversible membrane changes, and biochemical alterations that have the potential to affect the ability of RBCs to unload oxygen in the microcirculation. These changes worsen with increased storage duration and have been collectively referred to as the storage lesion. A number of observational studies and a few randomized prospective trials, have reported conflicting results as to whether these changes are clinically relevant.1 One large randomized trial published in 2015, however, comparing the use of fresh blood (storage duration, 6.1 ± 4.9 days) versus standard issue blood (storage duration, 22.0 ± 8.4 days) to critically ill adult patients, found no change in 90-day mortality.1 A second study, also published in 2015, compared the use of red cells stored for 10 days or less to red cells stored for 21 days or more in patients older than 12 years undergoing complex cardiac surgery and, again, found no change in the occurrence of multiple organ dysfunction.1

Blood Typing

Compatibility testing identifies clinically significant blood antigens and antibodies. Emergency clinicians should have a basic understanding of two common compatibility tests, the type and screen and crossmatch. The type and screen is typically ordered when an emergency clinician considers transfusion to be a possibility because it allows for the quicker selection of appropriate banked blood for complete crossmatch if a transfusion is later ordered. A type and crossmatch is ordered once a decision is made to administer blood or when administration is considered likely. Once a full type and crossmatch is ordered, the specified number of units will be held in reserve for a particular recipient until the blood products have been administered or the order has expired. Overuse of the type and cross order for patients at low risk of requiring blood products can overtax limited supplies, whereas judicious use of the type and screen order helps extend the capacity of the blood bank to meet the needs of a greater number of patients.

Type and Screen. A type and screen order requires the following tests to be carried out on a sample of the patient’s blood—ABO grouping, Rh typing, and antibody screen for unexpected antibodies (non–ABO/Rh antibodies).

RBC antigens include the ABO and related carbohydrate antigens (H, P, I, and Lewis), 48 Rh system antigens, and more than 200 non–ABO/Rh antigens. ABO grouping requires that the
recipient’s red cells be tested with anti-A and anti-B serum and that his or her serum be tested with A and B red cells. By about 6 months of age, most infants have formed antibodies against the A and B antigens they lack. Those with type AB blood form no ABO group antibodies. Patients with type O blood have antibodies against both. The major clinically significant Rh antigen is the D antigen. Rh typing is usually done by adding a commercial reagent (anti-D) to recipient RBCs. All infants, however, require that the initial standard compatibility testing include ABO and Rh typing as well as an antibody screen.7

The antibody screen identifies unexpected (non—ABO/Rh) antibodies in the patient’s serum. These develop in response to prior exposure to foreign RBC antigens during allogenic transfusion or pregnancy. To complete the antibody screen, the patient’s serum is combined with commercially prepared mixtures of red cells expressing clinically significant antigens. The incidence of these unexpected antibodies in the general population is low (<1%–2%), but a positive screen prompts further compatibility testing.

**Type and Crossmatch.** When a unit of blood is ordered for transfusion, a crossmatch follows the initial type and screen. In an ideal situation, blood identical to the patient’s own ABO and Rh group is used. Local blood supplies, however, might dictate that a nonidentical but compatible unit be used. Patients with blood group AB (who lack anti-A and anti-B antigens), for example, are known as universal recipients—they can receive blood from any of the ABO groups. Type O blood (lacking the A and B antigens), also known as universal donor blood, conversely, can be given to anyone. Rh compatibility is also important. Rh sensitization can occur in Rh-negative patients exposed to Rh-positive blood, and this sensitization in turn can result in hemolytic disease of the newborn with subsequent pregnancies.

The traditional crossmatch requires mixing the recipient’s serum with donor RBCs and observing for agglutination as a final compatibility test before transfusion. If the antibody screen is negative, an immediate spin crossmatch at room temperature serves as a final check for ABO incompatibility. A complete crossmatch is generally done before transfusion if the antibody screen is positive. This requires incubation to 37°C (98.6°F) and the addition of antihuman globulin (Coombs’ reagent) to promote agglutination. Many blood banks also substitute a computer crossmatch for patients whose blood has been tested at least twice in their system. Full compatibility testing takes time. An antibody screen and immediate spin crossmatch at a minimum requires approximately 45 to 60 minutes. This assumes a negative antibody screen followed by an immediate-spin crossmatch performed at room temperature. If the antibody screen is positive, the antibody is identified via more elaborate procedures, and a complete crossmatch (using a Coombs’ test with incubated serum) is required. This process can take up to several hours, or even days, an unacceptable delay in some emergent situations.

Although ABO compatibility is mandatory in all patients, non-ABO antibodies are less likely to cause immediate intravascular hemolysis.7 Universal (group O) PRBCs are therefore often used when RBCs are needed in hemorrhaging unstable patients before any testing can be done.8 Female patients receive O-negative blood to prevent hemolytic disease of the newborn unless there is no chance of subsequent pregnancy. All others may receive O-positive blood because, even if sensitization occurs, Rh antibodies generally do not fix complement; therefore, this would be unlikely to cause an acute life-threatening intravascular hemolytic reaction in the unlikely event that an Rh-negative recipient twice received an emergent transfusion of Rh-positive blood. Conversely, the universal type for fresh-frozen plasma (FFP) is type AB, which contains no antibodies to A or B antigens. Type-specific blood (with ABO and Rh testing) can generally be made available within 15 minutes of receiving a sample of the patient’s blood.

Similarly, if complete compatibility testing following a positive antibody screen would substantially delay transfusion of blood products to a critically ill patient, the emergency clinician may choose to bypass this step. Direct communication with the blood bank will facilitate determination of the best course of action.

**MANAGEMENT**

**Decision Making**

To select the most appropriate blood products in the emergency setting, emergency clinicians consider the cause of the deficit, severity of symptoms, likelihood of ongoing hemorrhage, tissue oxygen requirements, and the patient’s ability to compensate for decreased oxygen-carrying capacity, which is in turn influenced by the patient’s age, underlying medical conditions, and their hemodynamic stability. Clinical evaluation, including appearance (pallor, diaphoresis), mentation (alert, confused), heart rate, blood pressure, and nature of the bleeding (active, controlled, uncontrolled), can be supplemented by laboratory evaluation.

Numerous trials have now been done that support a restrictive strategy for red blood cell transfusions in stable patients, and I recommend using a trigger of 7 to 8 g/dL for euvoletic patients without significant ongoing hemorrhage.9 Randomized trials have also supported the use of prophylactic platelet transfusions for thrombocytopenia in stable, uncomplicated adult patients—those without fever, infection, or use of drugs known to inhibit platelet function—and I recommend that a platelet count less than 10,000/µL is an appropriate trigger for this purpose.10 For children, a similar threshold should prompt discussion with a pediatric hematologist about the need for platelet transfusion. A Cochrane Review has found that there are no high-quality trials regarding the use of FFP, and appropriate triggers for FFP are not as clearly defined.11 Further review of transfusion triggers and special circumstances will be covered below in the sections describing specific blood products.

Before a blood product can be infused, two qualified personnel check it at the bedside to prevent a potentially fatal clerical error. This check includes recipient and unit identification, as well as confirmation of compatibility, and the expiration date. Automated patient identification (eg, a bar code reader) may be substituted for the second individual if only one person is available.

If typed and crossmatched blood arrives with the patient from a transferring facility, it is important that the temperature be maintained between 1° and 10°C (33.8° and 50°F) during transport. If the blood is not used right away and the blood bank is asked to hold the blood for the patient, it is processed and crossmatched as for other issued blood and quarantined for 24 hours. It can be sent back to the blood bank to have this done only if it has been constantly maintained at a temperature between 1° and 10°C (33.8° and 50°F), all container seals are intact, and tubing segments have remained attached to the blood container.

**Pharmacology**

PRBCs are run through a filter with a large-bore intravenous (IV) line with normal saline. No other solutions should be used unless FDA (US Food and Drug Administration)—approved (eg, Normosol-R, pH 7.4; Plasma-Lyte 148). Lactated Ringer’s solution, for example, can lead to clotting secondary to the added calcium, and hemolysis may result from using an hypotonic solution such as a dextrose-containing fluid. Medications should also not be added to the unit or pushed through the transfusion line with blood components, although there is limited literature indicating that morphine, hydromorphone and meperidine can be
CHAPTER 111 Blood and Blood Components

given safely if there are no alternative sites available. The widespread use of antihistamines to prevent mild allergic reactions, and antipyretics to prevent febrile, nonhemolytic transfusion reactions, although poorly studied, is appropriate as long as the risk of side effects is considered. Most transfusions are given over 60 to 90 minutes, never longer than 4 hours. Unused blood should be returned promptly to the blood bank. Any units unrefrigerated for more than 30 minutes are discarded.

Research into Hgb-based oxygen carriers and perfluorocarbon emulsions has been ongoing but, as yet none are FDA-approved for general clinical use in the United States. Several problems remain unsolved. Hgb-based carriers, for example, have been found to cause vasoconstriction through nitric oxide (NO) scavenging, endothelin release, and peripheral α-adrenergic receptor sensitization. Perfluorocarbon emulsions require relatively high partial pressure of oxygen (PO2) levels and therefore require delivery of pure oxygen.

Devices and Techniques

Urgent transfusion situations require flow rates faster than gravity can provide. An administration set with an in-line pump that is squeezed by hand is the simplest method to speed infusion. Pressure bags (Fig. 111.1) are also available that completely encase the blood bag and apply pressure evenly. With high-pressure infusion, large-bore needles are recommended so that hemolysis is prevented. If only a small-gauge needle is available, the transfusion may be diluted with normal saline, but this may cause unwanted volume expansion. In elective transfusions, no significant hemolysis occurs when small-gauge needles are used if the maximum rate of infusion is less than 100 mL/hr. Autotransfusion (Fig. 111.2) may be used in the emergency setting in the event of severe chest trauma and was found in a large retrospective trial to be safe and effective. This strategy has numerous advantages—immediate availability, blood compatibility, elimination of donor to patient disease transmission, lower risk of circulatory overload, and fewer direct complications (eg, hyperkalemia, hypothermia, hypocalcemia, metabolic acidosis). It is also more acceptable to patients whose religious convictions prohibit transfusions. It is impractical in some settings, however, because of the limited number of appropriate trauma patients, training required to operate the equipment, and time required for equipment setup.

Thromboelastography, an older technology attracting renewed interest, particularly in trauma and sepsis in the emergency department (ED), may prove useful in guiding coagulation therapy but is not now widely used in the ED setting. A full description is beyond the scope of this chapter, but this test provides information on the function of platelets and coagulation factors, including fibrinogen.

Whole Blood

Intriguing reports on the use of fresh whole blood in military field hospitals have been published. In civilian practice in the United States, however, it has generally been unavailable and rarely used,
comprising only 0.15% of all transfusions in 2011.\textsuperscript{18} Interest in the use of whole blood has been growing, however, including the use of banked and fresh warm whole blood, despite the obvious logistic hurdles, and civilian trials have been proposed.\textsuperscript{19,20}

Packed Red Blood Cells

PRBCs are indicated only to improve oxygen delivery to tissues at the microvascular level and thus improve intracellular oxygen consumption, yet definitive demonstration of the efficacy of red cells for this purpose (or improved clinical outcomes) has proven elusive.\textsuperscript{21} A definitive randomized prospective study in which RBCs are withheld completely from one treatment group is unlikely to be done at this point.

I agree with the recommendations published in 2012 by the AABB (formerly, the American Association of Blood Banks), which were based on a systematic review of trials published between 1950 and February 2011. This review found strong support for using a restrictive transfusion strategy (7–to 8 g/dL) for most stable hospitalized patients.\textsuperscript{22} It was also recommended that transfusion decisions be influenced by symptoms and hemoglobin concentration and specifically addressed the case of hospitalized patients with preexisting cardiovascular disease, suggesting that emergency clinicians consider transfusion for these patients when they had symptoms or a hemoglobin level of 8 g/dL or less. Literature support for these additional recommendations was noted to be weak, however, and no specific recommendations could be made with regard to hospitalized, hemodynamically stable patients with an acute coronary syndrome.\textsuperscript{23}

For many patients, the decision to transfuse RBCs requires clinical judgment. The appropriate trigger for patients with active hemorrhage, for example, is not well established, although a trial in patients with acute gastrointestinal bleeding found somewhat improved survival outcomes overall in patients treated with a restrictive 7-g/dL transfusion trigger.\textsuperscript{24} I recommend transfusing any patient with ongoing severe hemorrhage and unstable vital signs, despite adequate fluid resuscitation. Conversely I would occasionally consider withholding transfusion for Hgb levels even lower than 6 g/dL in a young, healthy, asymptomatic patient at low risk for further bleeding. Another interesting area of investigation is the use of physiologic transfusion triggers (eg, lactate, mixed venous oxygen saturation), but further research is needed.\textsuperscript{25}

Fresh-Frozen Plasma

A unit of FFP contains all clotting factors and typically has a volume of 200 to 250 mL. It must be ABO compatible and is administered through blood tubing. FFP is given within 24 hours of thawing.

Indications for FFP are based primarily on observational trials and expert opinion.\textsuperscript{26} These indications seem reasonable based on current evidence; coagulopathy of trauma, hemorrhaging patients with coagulopathy resulting from hepatic dysfunction or disseminated intravascular coagulation (DIC), plasma exchange for thrombotic thrombocytopenic purpura (TTP), and emergency reversal of a vitamin K antagonist in the presence of clinically significant hemorrhage.\textsuperscript{27} It is worth noting, however, that the therapeutic effect is difficult to predict. A large volume of FFP is needed to reverse coagulopathy caused by vitamin K antagonism (at least 10 mL/kg, and perhaps as much as 30 mL/kg), enough for an older patient with congestive heart failure to develop pulmonary edema. Guidelines published by the American College of Chest Physicians have recommended that prothrombin complex concentrate (PCC) be used for the reversal of an elevated international normalized ratio (INR) in patients with life-threatening bleeding or intracranial hemorrhage, and available evidence has shown that a more rapid normalization of the INR in these patients occurs with the administration of PCC rather than FFP. Both three- and four-factor PCC products are now FDA-approved in the United States, with four-factor products containing all the vitamin K–dependent clotting factors, whereas three-factor products lack factor VII. A systematic review comparing three- and four-factor PCC in patients with serious warfarin-associated bleeding has found that the four-factor product is more reliable in reducing the INR to below 1.5 within 1 hour, and I recommend its use, when available.\textsuperscript{28} I also recommend that all patients with life-threatening warfarin-associated hemorrhage also receive 10 mg of vitamin K by slow IV infusion (no faster than 1 mg/min).

As noted below in the section on massive transfusions, evidence from retrospective trials has supported increased use of FFP in patients anticipated to require more than 10 units of PRBCs. This should not be generalized to all patients receiving a transfusion, however. A retrospective case-control trial of 1716 transfused trauma patients receiving fewer than 10 units of blood has found that the administration of FFP is associated with no survival benefit but has a higher risk of complications, including acute respiratory distress syndrome, pneumonia, sepsis, and multiple organ dysfunction.\textsuperscript{29}

FFP is typically not recommended for volume expansion, nonurgent reversal of a vitamin K antagonist, or treatment for abnormal INR from any cause in the absence of bleeding. Likewise, limited available evidence has failed to support the use of FFP in patients with an elevated INR before invasive procedures such as central line placement and lumbar puncture, although it is common practice to administer FFP for an INR greater than 1.5 to 2.0.\textsuperscript{2} One problem has been that the INR often proves to be a poor predictor of clinical bleeding.

If a specific factor deficiency is identified (eg, hemophilia), targeted replacement of that factor, if available, is usually more practical. Crossmatching is generally unnecessary for platelet transfusions, but Rh-negative patients are treated with Rh-negative platelets because there may be enough red cells in the platelet concentrate to cause Rh sensitization. The use of leukoreduced platelets has been shown to reduce the risk of human leukocyte antigen (HLA) sensitization and is therefore beneficial in patients receiving frequent platelet transfusions. Once sensitization has occurred and patients have developed immune-mediated platelet refractoriness, various management strategies may be considered in consultation with a hematologist, including HLA-based donor selection or platelet crossmatching.

Platelet transfusions have traditionally been given prophylactically when the count is less than 10,000/µL; this includes a margin of safety because it appears that hemostasis is well maintained, even at counts of 5000/µL, a threshold sometimes used for stable afebrile inpatients. There have been no large randomized trials on which to base recommendations for the use of prophylactic platelet transfusion before invasive bedside procedures such as lumbar puncture or central line placement.

Retrospective data have supported the safety of performing lumbar puncture with platelet counts as low as 10,000/µL. For central line placement, a platelet count of 20,000 to 30,000/µL is generally considered adequate, and at least one retrospective study has supported a threshold of 20,000/µL.\textsuperscript{28} For major surgery, a count of 50,000/µL is acceptable, although higher cutoffs (100,000/µL) are often used for high-risk procedures, such as those done on the eye or brain.\textsuperscript{3} Transfusing red cells can improve platelet function in anemic patients as the red cells push platelets to the periphery of vessels and closer to the endothelium.\textsuperscript{27}

Lastly, when thrombocytopenia results from immune-mediated platelet destruction caused by idiopathic thrombocytopenic purpura or TTP, transfusion is generally ineffective, although it may still be considered in the presence of life-threatening hemorrhage. If immune-mediated destruction is a result of HLA
sensitization from prior transfusions, a variety of strategies may be helpful, including the use of completely or partially HLA-matched platelets. Consultation with a hematologist can be helpful in such cases.

OUTCOMES

Safety and Effectiveness

See Table 111.1 for safety considerations. In an average adult, 1 unit (450 mL) of PRBCs increases the Hgb level by about 1 g/dL, or the hematocrit by about 3%. A similar increase in pediatric patients is obtained by administering 10 mL/kg.

One unit of activity for any coagulation factor is equal to the clotting activity found in 1 mL of FFP. Appropriate dosing of FFP has not been well grounded in evidence from clinical trials. As noted e, in massive transfusion, many centers now use FFP in a 1:1 ratio with red cells. For other indications, it seems reasonable to start with infusions of 10 to 30 mL/kg, realizing that results will be somewhat unpredictable, and follow-up laboratory and clinical assessment will be necessary to guide further management. Although not evidence-based, platelets are often given to adults in a dose of 6 units of platelet concentrate (a so-called six-pack of platelets) and in children at a dose of 1 unit/10 kg of body weight, an amount expected to raise the platelet count by about 40,000 to 60,000/µL. Because hemostasis is maintained with

<tr>
<td>Acute intravascular hemolysis</td>
<td>1:76,000</td>
<td>Intravascular hemolytic transfusion reaction is the most serious transfusion reaction. It generally results from ABO incompatibility, usually caused by clerical error. The resulting antigen-antibody reaction leads to the intravascular destruction of transfused red cells, producing hemoglobinemia and hemoglobinuria.</td>
<td>The onset of symptoms is immediate and may include fever, chills, headache, nausea, vomiting, sensation of chest restriction, severe joint or low back pain, burning sensation at the site of the infusion, and feeling of impending doom. Clinical effects can include hypotension, DIC, and acute tubular necrosis.</td>
<td>Treatment requires stopping the transfusion immediately, replacing all old tubing with new, and initiating vigorous crystalloid fluid therapy; vasopressors if the patient remains symptomatic. Diuretic therapy can also be used to maintain urine output at 1–2 mL/kg/hr. Blood and urine specimens are sent to the laboratory, as well as the remainder of the transfusion and blood tubing. The diagnosis can be confirmed by detection of free Hgb in blood and urine and a positive result of Coombs’ test on posttransfusion, but not pretransfusion, specimens.</td>
</tr>
<tr>
<td>Febrile nonhemolytic transfusion reaction (FNHTR)</td>
<td>0.1%–1%</td>
<td>It is defined as a temperature elevation of 1°C (33.8°F) or higher that occurs with transfusion and for which no other medical explanation is found. Reactions are believed to result from antileukocyte antibodies, usually as a result of prior transfusion.</td>
<td>Fever, chills, and occasionally rigors</td>
<td>The increasing use of leukoreduced RBCs can decrease the risk of this reaction and lends further support to the use of prestorage leukoreduction. If a febrile reaction occurs in a first-time transfusion, it should be treated as an acute hemolytic reaction until proven otherwise. For recurrent reactions, treatment is symptomatic with antipyretics and antihistamines. Patients with severe chills and rigors may also benefit from analgesics. Pretreatment with antipyretics is appropriate for patients with recurrent reactions.</td>
</tr>
<tr>
<td>Mild allergic reactions</td>
<td>1%–3%</td>
<td>Urticaria, or hives, may occur during a transfusion without other signs or symptoms and with no serious sequelae. It is generally attributed to an allergic, antibody-mediated response to a donor’s plasma proteins.</td>
<td>Pruritis, urticaria</td>
<td>The transfusion does not need to be stopped, and treatment with an antihistamine is usually sufficient. Pretreatment of patients with recurrent mild allergic reactions with an antihistamine is common practice and appropriate for most patients.</td>

</tbody>
</table>
| **Transfusion-related acute lung injury (TRALI)**<sup>37,38</sup> | 1:1,200–1:190,000; now the leading cause of transfusion-related mortality reported to the FDA | TRALI has been defined as new acute lung injury (ALI) occurring during or within 6 hr after a transfusion without temporal relationship to an alternative explanation for ALI, and resulting in the following clinical findings:  
  - Bilateral pulmonary edema  
  - Hypoxemia (ratio of arterial oxygen concentration to fraction of inspired oxygen \([\text{PaO}_2/\text{FiO}_2]\) ≤ 300, or oxygen saturation < 90% as measured by pulse oximetry on room air). If there is an alternate explanation, the diagnosis of possible TRALI is appropriate.  
A proposed cause includes a reaction between transfused antibodies and leukocytes in the recipient, as well as the effects of biologically active factors that accumulate in stored blood (cytokines and lipids). | Clinical effects can include noncardiogenic pulmonary edema, with dyspnea, hypoxemia, and bilateral infiltrates on the chest radiograph. Fever, hypotension, and transient leukopenia may also be seen. | One strategy suggested for reducing TRALI has been to use only male donors for plasma to avoid allotypic leukocyte antibodies, which can occur in women as a result of prior pregnancies, or to screen for these antibodies and exclude donors when the antibodies are found. Stop the transfusion, notify the blood bank, and provide respiratory support, which may include intubation and mechanical ventilation. It is safe to continue transfusion of blood products from a different donor. Complete resolution is usually seen within 48–96 hours. Overall prognosis is better than would be expected with many other causes of ALI, with a reported mortality rate of 6% in one series. |
| **Extravascular hemolytic transfusion reaction** | 1:2,500–1:1,000 | This can result from a non-ABO-mediated immune response, usually caused by an anamnestic response in a patient previously sensitized to red cell antigens by transfusion, pregnancy, or transplantation. Less commonly, primary alloimmunization can occur after transfusion. | Clinical effects can include fever, anemia, and jaundice. Symptoms are not usually severe, but rare cases of oliguria or DIC do occur. Hemoglobinemia and hemoglobinuria are generally absent. | Treatment is primarily supportive, but the blood bank should be notified. |
| **Transfusion-associated graft-versus-host disease** | Rare | This rare but usually fatal complication, results when transfused lymphocytes proliferate and attack the recipient. Cell-mediated immunodeficiency puts patients at risk, as does having an HLA type that is identical between donor and recipient (most often seen between first-degree relatives). | Symptoms begin 3 to 30 days after transfusion and include fever, erythematous skin rash, diarrhea, elevated liver enzyme levels, and pancytopenia. | Mortality is greater than 95%. Efforts are directed at prevention by using gamma irradiation of all cellular components, which renders the donor lymphocytes incapable of proliferating. The use of leukocyte-poor components is also advocated. This condition should be kept in mind when transfusion is being considered for these high-risk patients:  
- Congenital immunodeficiency  
- Hematologic malignancy  
- Stem cell transplantation  
- Treatment with purine analogues (eg, fludarabine)  
- Directed donor products from a close relative  
Consult a hematologist when deciding whether to use irradiated cellular components in these high-risk groups. |

platelet counts as low as 5,000/μL, it seems likely that smaller, more frequent platelet transfusions should be equally efficacious but more cost-effective, particularly in hospitalized patients. This practice is supported by a randomized trial that enrolled nearly 1300 patients undergoing prophylactic platelet transfusion, which demonstrated no increase in bleeding complications with the use of a low, medium, or high dose of platelets (amounts corresponding to roughly 2, 4, or 6 units of platelet concentrate). This may be impractical in outpatients, for whom increasing the frequency of transfusion can be more of a burden, and discussion with the patient’s hematologist is often helpful.

### Complications

#### Adverse Effects of Massive Transfusions

When the clinician anticipates large and ongoing blood losses, complications resulting from massive transfusion should be considered. Massive transfusion has no formal definition, but administration of at least 10 units of RBCs in 24 hours is a commonly used cutoff point. Although patients receiving any amount of blood are susceptible to a variety of infectious, physiologic, and immunologic insults, this section will discuss adverse effects that are particularly associated with massive transfusion, as well as management strategies that attempt to address these concerns.

Some of the complications of massive transfusion are well understood and easily managed. Hypothermia is common in these patients and can reduce clotting factor activity. Warmed IV fluids, blood warmers, and warming lights and blankets are often needed. Frequent laboratory testing will identify electrolyte disturbances (low magnesium and calcium levels; high and low potassium levels), which are in general treated in a standard fashion by replenishing deficits or administering calcium for hyperkalemia. Acidosis is a common finding with massive hemorrhage but can also be caused by hypoperfusion, and the contribution of transfused blood to acidosis is thought to be variable. Citrate from banked blood, for example, is metabolized in the liver to bicarbonate, which can sometimes result in metabolic alkalosis. With rapid infusion or reduced hepatic function, however, this pathway can be overwhelmed, and the net effect of infusing large amounts of citrate can be worsening metabolic acidosis. A rational response to metabolic acidosis is to optimize oxygen delivery and ventilation. The benefits of administering sodium bicarbonate are unproven, and I do not recommend it.
Patients receiving massive transfusion are also prone to coagulopathy and thrombocytopenia. Consumption and dilution of clotting factors and platelets occur in these patients owing to ongoing hemorrhage, fluid boluses, and transfusion of PRBCs. This undoubtedly plays a role in the coagulopathy of trauma, but coagulopathy often occurs in massive trauma, even before these mechanisms have taken effect. A number of retrospective reports have suggested that a more proactive approach to administering plasma and platelets in massive transfusion is associated with better outcomes. In response, many institutions have adopted massive transfusion protocols that call for plasma and often platelets, to be given in a 1:1 ratio with RBCs. A systematic review has concluded that the available evidence could not support any definite recommendations regarding specific ratios of blood components in massive transfusion. The only large, multicenter randomized clinical trial (published early in 2015), the PROPPR trial, compared the use in massively transfused trauma patients of a 1:1:2 ratio (plasma to platelets to PRBCs) versus a 1:1:1 ratio and found no difference in mortality at 24 hours or 30 days, although fewer patients in the 1:1:1 group had died of exsanguination at 24 hours.

When set ratios are not used, clinical assessment and judgment often augment laboratory values such as the INR, partial thromboplastin time, and fibrinogen and platelet counts, because there is no direct evidence supporting any particular threshold for platelet or coagulation factor replacement in patients with severe hemorrhage. Commonly recommended goals in this setting would be to consider maintaining an INR below 1.5, fibrinogen level higher than 1 to 2 g/L, and platelet count above 50,000 to 100,000/µL.

**Adverse Effects of Nonmassive RBC Transfusion**

See Table 111.1.

### KEY CONCEPTS

- Red blood cell transfusion is indicated only to increase oxygen delivery at the tissue level.
- One unit of PRBCs can be expected to raise an adult’s hemoglobin level by 1 g/dL. A similar increase is expected in children following the transfusion of 10 mL/kg of PRBCs.
- Large randomized controlled trials have supported newer, restrictive, red cell transfusion strategies. Pending further trials, a transfusion trigger of 7 to 8 g/dL is appropriate for most stable hospitalized patients.
- Platelet transfusions are typically used prophylactically for counts less than 10,000/µL in patients without bleeding and for counts less than 50,000/µL for patients undergoing surgery. Patient’s undergoing high-risk surgical procedures, such as neurosurgery, are often transfused for platelet counts less than 100,000/µL.
- Prospective and retrospective reports have suggested a benefit to massive transfusion protocols, and the results of the PROPPR trial comparing a 1:1:1 ratio of FFP to platelets to PRBCs to a 1:1:2 ratio showed no difference in mortality at 24 hours or 30 days, although a post hoc analysis did find fewer deaths by exsanguination in the first 24 hours with a 1:1:1 ratio.
- FFP is not recommended for volume expansion, nonurgent reversal of a vitamin K antagonist, or treatment for an abnormal INR from any cause in the absence of bleeding. PCC is recommended for these cases, and four-factor concentrates are preferred, if available.
- Intravascular hemolytic transfusion reaction is the most serious transfusion reaction. It is usually the result of ABO incompatibility and typically results in immediate symptoms that can include fever, chills, headache, nausea, vomiting, sensation of chest restriction, severe joint or low back pain, burning sensation at the site of the infusion, and feeling of impending doom.
- Transfusion-related acute lung injury is now the leading cause of transfusion-related mortality reported to the FDA.
- Improved techniques for selecting and testing blood donors have dramatically reduced the risk of viral transmission of disease by transfusion. It is believed that the blood supply in the United States has never been safer.

CHAPTER 111: QUESTIONS & ANSWERS

111.1. Which one of the following immune-mediated transfusion reactions is most common and least serious?

A. Allergic reaction
B. Extravascular hemolysis
C. Febrile reaction
D. Intravascular hemolysis
E. Transfusion-related acute lung injury

Answer: C. Febrile transfusion reaction is the most common and least serious transfusion reaction. It is defined as a 1°C (33.8°F) or higher temperature elevation that occurs with transfusion and for which no other medical explanation is found. Reactions are believed to result from antileukocyte antibodies, usually as a result of prior transfusion. Treatment is symptomatic with analgesics, antipyretics, and antihistamines.

111.2. An 81-year-old woman with a history of congestive heart failure (CHF) requires transfusion. She suffers from chronic anemia and is currently normotensive but tachypneic because of her CHF. You want to minimize the risk of fluid overload by transfusing slowly. Over how many hours can the transfusion be given?

A. 2
B. 3
C. 4
D. 6
E. 12

Answer: C. Chronically anemic, normovolemic older patients are at greatest risk for developing congestive heart failure with the rapid infusion of blood. Transfusing more slowly (over a period of 4 hours) and administering diuretics are useful in preventing this complication.

111.3. Which of the following transfusion reactions is usually the result of ABO incompatibility, usually caused by human error, and considered to be the most serious transfusion reaction?

A. Extravascular hemolytic transfusion reaction
B. Febrile transfusion reaction
C. Intravascular hemolytic transfusion reaction
D. Transfusion-associated graft-versus-host disease
E. Transfusion-related acute lung injury

Answer: A. An extravascular hemolytic transfusion reaction is considered to be the most serious of the transfusion reactions. It is usually caused by ABO incompatibility and is most often secondary to human error.

111.4. A 15-year-old male is receiving transfusion of packed red blood cells after a traumatic injury when he complains of itching. On examination, hives are found, and soon the patient develops difficulty breathing, tachypnea, tachycardia, and hypotension. The transfusion is stopped.
Which of the following medications should be administered?

A. Acetaminophen  
B. Epinephrine and corticosteroids  
C. Furosemide  
D. RhoGAM  
E. Third-generation cephalosporin

**Answer:** B. Occasionally, full anaphylaxis may be caused by an anti-immunoglobulin A (IgA) reaction to IgA in the donor’s blood components. The patient is likely to have a genetic IgA deficiency. The presentation is similar to anaphylactic reactions from other causes. Treatment is with epinephrine and corticosteroids. Washed red blood cells (RBCs) and plasma products from IgA-deficient individuals can be used to avoid recurrence with subsequent transfusions.
ANEMIA

Principles

Background and Importance

Anemia is an absolute decrease in the number of circulating red blood cells (RBCs). The diagnosis is made when laboratory measurements fall below accepted normal values (Table 112.1). Anemia is divided into two broad categories: emergent, having immediate life-threatening complications; and nonemergent, with less imminent danger to the patient. Factors other than the absolute number of circulating RBCs may place the patient in one category or another (eg, rate of onset and underlying hemodynamic reserve of the patient). Both groups necessitate a sound diagnostic approach, but emergent anemia may require supportive therapy concomitant with or in advance of the definitive diagnosis. Although patients with nonemergent anemia are usually referred to a specialist, the urgency of consultation depends predominantly on the patient's hemodynamic tolerance of the anemia.

Anatomy and Physiology

The major function of the RBC is oxygen transport from the lung to the tissue and carbon dioxide transport in the reverse direction. Oxygen transport is influenced by the amount of hemoglobin, its oxygen affinity, and blood flow. An alteration in any of these major components usually results in compensatory changes in the other two. For example, a decrease in hemoglobin is compensated by both inotropic and chronotropic cardiac changes that result in increased blood flow and decreased hemoglobin affinity at the tissue level, thereby allowing more oxygen release. Due to disease severity or underlying pathologic conditions, these compensatory responses may fail, resulting in tissue hypoxia and cell death.

Anemia stimulates the compensatory mechanism of erythropoiesis controlled by the hormone erythropoietin, which is a glycoprotein produced in the kidney (90%) and the liver (10%). It regulates the production of RBCs by controlling differentiation of the committed erythroid stem cell and is stimulated by tissue hypoxia and products of RBC destruction during hemolysis. Elevated in many types of anemia, erythropoietin enhances the differentiation of erythroid progenitors.

Bone marrow contains pluripotent stem cells that can differentiate into erythroid, myeloid, megakaryocytic, and lymphoid progenitors. When the late normoblast extrudes its nucleus, it still contains a ribosomal network, which identifies the reticulocyte. The reticulocyte retains its ribosomal network for approximately 4 days, 3 days of which are spent in bone marrow and 1 day in the peripheral circulation. The RBC matures as the reticulocyte loses its ribosomal network and circulates for 110 to 120 days. The erythrocyte is then removed by macrophages that detect senescent signals. Under steady-state conditions, RBC mass remains constant because an equal number of reticulocytes replace the destroyed, senescent erythrocytes.

Pathophysiology

Common sites of blood loss in trauma include the pleural, peritoneal, pelvic, and retroperitoneal spaces. In nontraumatic circumstances, especially in patients receiving anticoagulants, the gastrointestinal tract, retroperitoneal space, uterus, and adnexa need to be considered.

Certain unusual hemolytic conditions can also cause rapid intravascular destruction of RBCs (Box 112.1). More common are patients with chronic compensated hemolytic anemia (eg, sickle cell disease), who may decompensate as a result of decreased erythrocyte production triggered by a viral infection.

Beyond red cell destruction, carbon monoxide poisoning, methemoglobinemia from nitrates, cyanemoglobin from cyanide, and sulfhemoglobinemia from hydrogen sulfide may severely decrease functional hemoglobin. These patients often have fatigue, altered mental status, shortness of breath, and other manifestations of hypoxia without signs of RBC loss or volume depletion.

Clinical Features

The clinical manifestation of anemia depends on how rapidly the hematocrit falls and also on the patient's ability to compensate. Clinical signs and symptoms of acute blood loss include tachycardia, decreased blood pressure, postural hypotension, lightheadedness, increased heart rate, and increased respiratory rate. Complaints of thirst, altered mental status, and decreased urine output may also be present. The patient's age, concomitant illness, and underlying hematologic, cerebral, and cardiovascular status tremendously influence the presenting clinical findings. Children and young adults may tolerate significant blood loss with unaltered vital signs until a precipitant hypotensive episode occurs. Elderly patients commonly have underlying disease states that compromise their ability to compensate for blood loss. Pertinent elements of the history and physical examination of patients with acute anemia are listed in Box 112.2.

In contrast, nonemergent anemias are usually seen in ambulatory patients complaining of fatigue and weakness, irritability, headache, postural dizziness, angina, decreased exercise tolerance, shortness of breath, or decreased libido. For patients without evidence of acute bleeding or emergent condition, elements of history and physical examination may help identify the cause (Box 112.3). When the anemia is of slow onset, the patient may adapt until the hemoglobin is very low. Most of these patients do not need immediate stabilization and can be further evaluated as outpatients.

Differential Diagnosis

The differential diagnosis of anemia is facilitated by classification of the anemia into one of three groups: decreased RBC production, increased RBC destruction, and blood loss. A complementary approach uses RBC morphology and indices. Figure 112.1 presents an algorithm for the evaluation of anemia.
Hematology and Oncology

The MCHC index is a measure of the concentration of hemoglobin. Low values represent hypochromia, whereas high values are noted only in patients with decreased cell membrane relative to cell volume, such as in the case of spheroctosis. An additional index is the RBC distribution width (RDW), a measure of RBC homogenicity. RDW is automatically calculated as the standard deviation of MCV divided by MCV multiplied by 100. A normal RDW is 13.5 ± 1.5%. The RDW is elevated in anemias caused by nutritional deficiencies; however, it is not specific for any abnormality.

Measurements of coagulation status, electrolytes, glucose, blood urea nitrogen, and creatinine are useful in the diagnosis of underlying disease processes that may relate to the patient’s anemia. Because values of folate, vitamin B₁₂, iron, total iron-binding capacity, reticulocytes, and direct antiglobulin (Coombs test) are altered by transfusion, pretreatment samples should be obtained in patients where the cause of anemia is not known.

Diagnostic Testing

In a patient suspected of acute blood loss, samples for the following initial laboratory tests are drawn:
- Complete blood count and peripheral smear
- Blood sample for type and crossmatch
- Prothrombin time and international normalized ratio
- Partial thromboplastin time
- Electrolyte levels
- Glucose level (if the patient has altered consciousness)
- Creatinine level
- Urinalysis for free hemoglobin
- Clotting and uncotted blood samples for later testing

If possible, a hematocrit or hemoglobin should be measured in the emergency department (ED). Although it may take hours before the hematocrit or hemoglobin correctly reflects the degree of blood loss, the initial value is useful in determining a baseline. On occasion, this value reveals an underlying anemia with superimposed acute blood loss. Depending on severity, a blood sample is sent for type and crossmatch. Peripheral smear interpretation is done on pretreatment blood samples.

The initial laboratory evaluation for a patient with nonemergent anemia also includes a complete blood count with leukocyte differential, reticulocyte count, peripheral smear (Fig. 112.2), and RBC indices, including mean corpuscular volume (MCV), mean corpuscular hemoglobin (MCH), and mean corpuscular hemoglobin concentration (MCHC). RBC indices are useful in classifying anemias caused by a production deficit (Table 112.2). MCV is a measure of RBC size; decreases and increases reflect microcytosis and macrocytosis, respectively. MCH incorporates both RBC size and hemoglobin concentration. It is influenced by both and is the least helpful of the indices. The MCHC index is a measure of the concentration of hemoglobin. Low values represent hypochromia, whereas high values are noted only in patients with decreased cell membrane relative to cell volume, such as in the case of spherocytosis. An additional index is the RBC distribution width (RDW), a measure of RBC homogenicity. RDW is automatically calculated as the standard deviation of MCV divided by MCV multiplied by 100. A normal RDW is 13.5 ± 1.5%. The RDW is elevated in anemias caused by nutritional deficiencies; however, it is not specific for any abnormality.
**BOX 112.3**

**History and Physical Examination for Nonemergent Anemia**

**HISTORY**

**Symptoms of Anemia**
- Chest pain, decreased exercise tolerance, dyspnea
- Weakness, fatigue, dizziness, syncope

**Bleeding Diathesis**
- Bleeding after trauma, injections, tooth extractions
- Spontaneous bleeding, such as epistaxis, menorrhagia
- Spontaneous purpura and petechiae

**Sites of Blood Loss**
- Respiratory: Epistaxis, hemoptysis
- Gastrointestinal: Hematemesis, hematochezia, melena
- Genitourinary: Abnormal menses, pregnancies, hematuria
- Skin: Petechiae, ecchymoses

**Intermittent Jaundice, Dark Urine**

**Dietary History**
- Vegetarianism
- Poor nutrition

**Drug Use and Toxin Exposure, Including Alcohol**

**Racial Background, Family History**

**Underlying Disease**
- Uremia, liver disease, hypothyroidism
- Chronic disease states, such as cancer, rheumatic or renal disease
- Previous surgery

**Miscellaneous**
- Previous treatment of anemia
- Weight loss
- Back pain

**PHYSICAL EXAMINATION**

**Skin**
- Pallor
- Purpura, petechiae, angiomas
- Ulcerations

**Eye**
- Conjunctival jaundice, pallor
- Funduscopic hemorrhage, petechiae

**Oral**
- Tongue atrophy, papillary soreness

**Cardiopulmonary**
- Heart size, murmurs, extra cardiac sounds
- Rales, other signs of pulmonary edema

**Abdomen**
- Hepatomegaly, splenomegaly
- Ascites
- Masses

**Lymph Nodes**

**Neurologic**
- Altered positions or vibratory sense
- Peripheral neuritis

**Rectal and Pelvic**

**Management**

Stabilization of emergent anemia commonly runs parallel to assessment. If the signs and symptoms suggest potential life-threatening conditions, intravenous lines are placed.

**Disposition**

Criteria for the admission of patients with nonemergent anemia are shown in Box 112.4.

**BOX 112.4**

**Admission Criteria for Nonemergent Anemia**

Developing cardiac symptoms, such as shortness of breath or chest pain, or neurologic symptoms

Initial unexplained hemoglobin value less than 8–10 g/dL or hematocrit less than 25% to 30%*

Major difficulty in obtaining outpatient care for patients whose hemoglobin levels are significantly low or when comorbidity is present*

*Consider observation unit for initial evaluation and stabilization.

**ANEMIAS DUE TO DECREASED RED BLOOD CELL PRODUCTION**

**Principles**

**Background and Importance**

Anemias caused by decreased RBC production are insidious in onset and are associated with decreased reticulocyte count. A subclassification by indices of anemias caused by decreased RBC production is listed in Box 112.5. The RBC indices and a peripheral smear are useful in securing the diagnosis. The definitive
Because changes in RBC size and hemoglobin content occur only after bone marrow and cytochrome iron stores are depleted, a patient may have early symptoms of iron deficiency (eg, fatigue) without manifesting changes in RBC structure.

**Clinical Features.** Most anemias secondary to iron deficiency are nonemergent. The symptoms related to anemia are secondary to the body’s ability to adapt to the low hemoglobin levels over time and the eventual inability of the tissues to receive enough oxygen for their metabolic demands. The clinical features of iron deficiency anemia are the same as described earlier.

**Diagnostic Testing.** The diagnosis is made by laboratory evaluation of the fasting level of serum iron, serum ferritin, and total iron-binding capacity. The laboratory interpretation and pitfalls are outlined in Table 112.3. A concentrated search for occult blood loss is vital.

**Management.** Therapy consists of oral iron replacement. A cost-effective form is ferrous sulfate. The dosage is 300 mg for adults (60 mg of elemental iron) or 3 mg/kg/day for children. This medication is generally well tolerated, although it may cause

**Management.** Therapy consists of oral iron replacement. A cost-effective form is ferrous sulfate. The dosage is 300 mg for adults (60 mg of elemental iron) or 3 mg/kg/day for children. This medication is generally well tolerated, although it may cause
The patient may experience a sense of improvement in as few as 24 hours. Reticulocytosis appears during a 3- or 4-day period in children but may take more than 1 week in adults. The hemoglobin concentration rises on a similar schedule. Explanations for response failures to iron therapy include the following: patient noncompliance with iron supplementation, insufficient replacement, incorrect diagnosis, or there is an additional process complicating the iron deficiency.

**Thalassemia**

**Principles.** The hemoglobin molecule is present as two paired globin chains. Each type of hemoglobin is made up of different globins. Normal adult hemoglobin (HbA) is made up of two alpha chains and two beta chains ($\alpha_2 \beta_2$). HbA2 is $\alpha_2 \delta_2$ and is a variant of hemoglobin A and has two alpha and two delta chains. Fetal hemoglobin (HbF) is $\alpha_2 \gamma_2$. A separate autosomal gene controls each globin chain.

**BOX 112.5**

Differential Diagnosis of Anemias Caused by Decreased Red Blood Cell Production

Subclassification by Red Blood Cell Indices

**HYPOCHROMIC MICROCYTIC ANEMIAS (DECREASED MCV AND HEMOGLOBIN CONCENTRATION)**

- Iron deficiency
- Thalassemia
- Sideroblastic anemia or lead poisoning
- Chronic disease (e.g., cancer, renal or inflammatory disease); normochromic and normocytic indices often found

**MACROCYTIC (ELEVATED MCV)**

- Vitamin B12 deficiency
- Folate deficiency
- Liver disease
- Hypothyroidism

**NORMOCYTIC (NORMAL MCV AND HEMOGLOBIN CONCENTRATION)**

- Primary bone marrow involvement: Aplastic anemia, myeloid metaplasia with myelofibrosis, myelophthisic anemia
- Resulting from underlying disease: Hypoendocrine state (thyroid, adrenal, pituitary), uremia, chronic inflammation, liver disease

MCV, Mean corpuscular volume.
Pathophysiology. Thalassemia is a genetic autosomal defect reflected by the decreased synthesis of globin chains. Deletions in these globin genes result in an absence or decreased function of the messenger RNA that codes for that globin. The various globins (α, β, δ, and γ) may be affected by a number of genetic combinations. Decreased globin production in thalassemia results in decreased hemoglobin synthesis and ineffective erythropoiesis, which causes increased intramarow hemolysis with destruction of RBCs. Beta thalassemia has an excess of alpha-globins, leading to the formation of alpha-globin tetramers and alpha-thalassemia results in an excess of beta-globins, which leads to the formation of beta-globin tetramers called hemoglobin H. The abnormal formation of hemoglobin at various concentrations results in complications, such as red cell membrane breakage and hemoysis. Clinical classification is by phenotype: thalassemia may be major, intermedia, minor, or silent. Normal erythropoiesis has a 10% to 20% incidence of ineffective release, but ineffective release of erythropoiesis may double or triple in patients with thalassemia.

Clinical Features. Although many variations in thalassemia are possible, only three are commonly considered. Homozygous beta-chain thalassemia (thalassemia major) occurs predominantly in Mediterranean populations. It represents one of the most common single-gene disorders. The disease is characterized by severe anemia, hepatosplenomegaly, jaundice, abnormal development, and premature death. Patients are transfusion dependent and die as a result of iron deposition in tissues, particularly the myocardium, or infection. Heterozygous beta-chain thalassemia (thalassemia minor) is manifested as a mild anemia and most patients are asymptomatic. Alpha-thalassemia varies in spectrum from an asymptomatic carrier state to prenatal death. Four gene loci control this range. The tolerated forms are more commonly seen in Asians and African Americans.

Diagnostic Testing. Thalassemia is a microcytic, hypochromic anemia. Hypochromia, target cells, and basophilic stippling are noted on the peripheral smear. The MCV is commonly lower than seen with iron deficiency and serum iron levels are normal. The diagnosis is made with hemoglobin electrophoresis and genetic testing. Screening for carriers is performed by measurement of RBC indices and estimation of the HbA1 concentration. Prenatal diagnosis can be made by analysis of fetal blood or by fetal DNA obtained by chorionic villus sampling.

Management. Therapy consists of blood transfusions, where the goal of transfusion therapy include correction of anemia, ineffective erythropoiesis, mild to moderate anemia, and a dimorphic peripheral smear with hypochromic microcytes along with normal and macrocytic cells.

Clinical Features. Although sideroblastic anemia is found in a rare sex-linked hereditary form, the idiopathic form is a common type of refractory anemia in elderly patients. Pallor and splenomegaly may be noted, and iron staining of the peripheral smear may demonstrate iron-containing inclusion bodies in RBCs. Idiopathic sideroblastic anemia is considered a preleukemic state, and acute myelogenous leukemia develops in approximately 5%.

Differential Diagnosis. Secondary causes of sideroblastic anemia include toxins, such as chloramphenicol, isoniazid, and cycloserine, as well as diseases, such as hemolytic and megaloblastic anemia, infection, carcinoma, leukemia, and rheumatoid arthritis. The exact mechanisms of these causative agents and diseases are unknown. Lead poisoning, one reversible cause of sideroblastic anemia, may be suggested by basophilic stippling on the peripheral smear. Elevated blood lead levels are diagnostic. Alcohol abuse may also result in disordered heme synthesis, which can be corrected by alcohol cessation or by parenteral pyridoxal phosphate in cases of continued abuse. Oral pyridoxine may be ineffective because of impaired conversion to the active form in alcoholic patients.

Management. Some patients with primary sideroblastic anemia are deficient in pyridoxine (vitamin B6) and respond to treatment with 100 mg of pyridoxine three times a day. About two-thirds will respond but most remain anemic. These patients are susceptible to iron overload if long-term transfusion therapy is necessary, but they may respond to chelation. Treatment for secondary forms are supportive.

Anemia of Chronic Disease

Principles. Anemia of chronic disease is secondary to reduced RBC bone marrow production and reduced RBC survival time in the peripheral circulation. Malignancies, chronic inflammation, renal insufficiency, chronic heart failure, chronic obstructive lung disease, and infection are common causes.

Clinical Features. Symptoms are usually those related to the underlying disease and not from the anemia.

Differential Diagnosis. Anemia of chronic disease is common and typically normochromic, normocytic. It is characterized by low serum iron levels, low total iron-binding capacity, and normal or elevated ferritin levels. Bone marrow is normal, but staining reveals an abnormality in the mobilization of iron from reticuloendothelial cells. This anemia can be differentiated from iron deficiency by total iron-binding capacity, serum ferritin level, bone marrow examination, and nonresponsiveness to a trial of iron therapy. A complete search for occult blood loss is necessary during the evaluation of this diagnosis because iron deficiency may be superimposed.

Management. Because the hematocrit is seldom less than 25% to 30%, therapy is not usually required. Treatment should be directed at the underlying causes.

Macrocytic and Megaloblastic Anemias

Principles. The hematologic manifestation of a total-body alteration in DNA synthesis, megaloblastic anemia is caused by vitamin B12 and folate acid deficiency, which appears clinically in tissues with rapid cell turnover, including hematopoietic cells and those of mucosal surfaces, particularly in the gastrointestinal tract. This deficiency is characterized by ineffective erythropoiesis and pancytopenia. Vitamin B12 and folate deficiencies have different developmental histories, but the clinical result is similar. Differentiation of folate and vitamin B12 deficiencies usually depends on laboratory measurements.

Clinical Features. Table 112.4 lists a number of the problems associated with megaloblastic anemia and their underlying pathologic states. A unique feature of vitamin B12 deficiency is its...
Changes occur. Causes of folate deficiency are listed in Box 112.6. Therefore, a 2- to 4-month supply is available before megaloblastic anemia requires approximately 100 µg of oral folic acid per day. Parenteral administration is generally unnecessary because most cases are due to dietary deficiency. In contrast, malabsorption is the most common cause of vitamin B₁₂ deficiency, and parenteral therapy is initiated at 100 µg/day intramuscularly for the first 7 to 10 days. Thereafter, only monthly 100-µg doses are necessary. The response is often dramatic, with reticulocyte counts rising up 30% to 50% and normalization of RBC, white blood cell (WBC), and platelet counts in 6 to 8 weeks. We do not recommend vitamin B₁₂ or folate supplements in patients with undiagnosed anemia. Unfortunately, the routine injection of vitamin B₁₂ in the elderly is still a common practice.¹⁴

### Causes of Vitamin B₁₂ Deficiency

- Inadequate dietary intake
- Total vegetarianism: No eggs, milk, or cheese
- Alcoholism
- Inadequate absorption
- Absent, inadequate, or abnormal intrinsic factor, as seen in patients with pernicious gastrectomy and anemia; in anemia, autoimmune antibodies act against gastric parietal cells and intrinsic factor
- Abnormal ileum, as can occur in sprue and inflammatory bowel disease
- Inadequate use
- Enzyme deficiency
- Abnormal vitamin B₁₂-binding protein
- Increased requirement by increased body metabolism
- Increased excretion or destruction

Folic acid, absorbed in the duodenum and jejunum, is commonly found in green vegetables, cereals, and fruit. It may be destroyed completely by cooking. The body requires approximately 100 µg/day and usually stores 6 to 20 mg. Therefore, a 2- to 4-month supply is available before megaloblastic changes occur. Causes of folate deficiency are listed in Box 112.6. Most patients with folate deficiency have either an inadequate dietary intake, such as alcoholic patients, or increased use, as in pregnancy.

Vitamin B₁₂ is found in foods of animal origin and is absorbed in the ileum after binding to intrinsic factor, which is a glycoprotein secreted by gastric parietal cells. The adult requirement is 1 or 2 µg/day, with a body store of 5 mg. Therefore, megaloblastic changes may take up to 4 years to develop after cessation of vitamin B₁₂ intake. The various causes of vitamin B₁₂ deficiency are listed in Box 112.7. The most common cause is chronic malabsorption.

Megaloblastic anemia that is not responsive to folate or vitamin B₁₂ is commonly related to antimetabolites used in chemotherapy or rare inherited disorders of DNA synthesis.

Macrocytic anemias unrelated to megaloblastic changes are seen frequently. Liver disease, often associated with alcoholism, is the most common cause. Macrocytic target cells may be seen on the peripheral smear in conjunction with this disorder. Hypothyroidism and hemolysis may also be manifested as macrocytic anemia.

### Diagnostic Testing

Macrocytic anemia is suggested when the MCV is greater than 100 fL, but other criteria need to be met for megaloblastosis to be considered the cause of the macrocytic anemia. On the peripheral smear, large oval red cells (macroovalocytes) and hypersegmented polymorphonuclear neutrophils are diagnostic (Fig. 112.4). A bone marrow aspirate may reveal morphologic changes consistent with megaloblastic erythropoiesis.

Other potentially useful laboratory tests include vitamin B₁₂ and folate levels, red cell folate, and lactate dehydrogenase (LDH). Laboratory techniques, values, and interpretations are listed in Table 112.5. Screening tests to differentiate between megaloblastic anemia and macrocytic anemia of other causes include a peripheral smear for macro-ovalocytes, hypersegmented polymorphonuclear neutrophils, and the LDH level.

### Management

Because one deficiency may cause gastrointestinal absorption changes that beget other deficiencies, the emergency clinician may be forced to initiate therapy before the final diagnosis is made. However, it is important to obtain baseline laboratory specimens. The usual dosage for patients with megaloblastic anemia secondary to folate deficiency is 1 mg of oral folic acid per day. Parenteral administration is generally unnecessary because most cases are due to dietary deficiency. In contrast, malabsorption is the most common cause of vitamin B₁₂ deficiency, and parenteral therapy is initiated at 100 µg/day intramuscularly for the first 7 to 10 days. Thereafter, only monthly 100-µg doses are necessary. The response is often dramatic, with reticulocyte counts rising up 30% to 50% and normalization of RBC, white blood cell (WBC), and platelet counts in 6 to 8 weeks. We do not recommend vitamin B₁₂ or folate supplements in patients with undiagnosed anemia. Unfortunately, the routine injection of vitamin B₁₂ in the elderly is still a common practice.
Normochromic and Normocytic Anemias

**Principles.** The origin of normochromic and normocytic anemias secondary to decreased production is not as obvious as that of macrocytic and microcytic anemias, because the latter give clues to their origin by alterations in RBC indices. One hematologic parameter that can aid in the diagnosis of normocytic anemia associated with hypoproduction is the reticulocyte count, which reflects RBC bone marrow production. Reticulocytes are released from bone marrow every 1 to 3 days and contain residual RNA that can be detected by supravital staining. With an average MCV of 160 fL, sufficient numbers of reticulocytes can increase the MCV of the total erythrocyte count. The reticulocyte count is expressed as a percentage of the total RBC population and needs to be related (“corrected”) to the RBC count of the patient. The corrected reticulocyte count is equal to the measured percentage of reticulocytes times the patient’s hematocrit (%) divided by 45% (taken as the normal hematocrit). The normal range is 1% to 3%.

Normocytic anemia may be classified as being due to primary bone marrow involvement or a secondary marrow response to underlying disease.

**Differential Diagnoses.** Myelophthisic anemia is bone marrow failure resulting from replacement by an invading tumor, leukemia, lymphoma, or, rarely, granuloma. A more basic defect or inhibitor may complicate the problem because the degree of anemia cannot always be correlated with the extent of bone marrow invasion. Any patient with oncologic disease may develop this type of anemia. Useful clues are signs of extramedullary hematopoiesis, such as hepatosplenomegaly and a leukoerythroblastic peripheral smear demonstrating immature WBCs, nucleated RBCs, and poikilocytosis (teardrop-shaped red cells). The final diagnosis is made by bone marrow examination, and therapy is directed at the underlying disorder.

Myelofibrosis of unknown origin is the usual cause of primary bone marrow failure associated with extramedullary hematopoiesis. The diagnosis may be made by bone marrow examination. Treatment is supportive, although a splenectomy or alkylating agents may help treat complications of extramedullary blood cell production, such as hepatosplenomegaly.

The hypoplastic anemias of secondary origin are commonly seen as mild chronic anemias with low reticulocyte counts. They have a normal MCV and RDW. These are diagnoses of exclusion. Anemia of chronic disease may have microcytic or normocytic indices. It is associated with chronic inflammation (eg, rheumatoid arthritis, chronic infections such as tuberculosis and osteomyelitis, and malignant disease). Hypoendocrinism caused by hypothryoidism, hypoadrenalism, or hypopituitarism results in a hypometabolic state in which the bone marrow responds poorly to erythropoietin, and erythropoietin levels may be low. The anemia of chronic renal failure is thought to be caused by a number of factors including decreased erythropoietin production, hemolysis, suppression by dialyzable factors, and increased blood loss caused by platelet abnormalities. If necessary, it may be corrected by erythropoietin replacement therapy.15

Aplastic Anemia

**Principles.** Aplastic anemia is rare but may have severe manifestations. It is suspected in anemic patients with normal indices, a low reticulocyte count, and a history of exposure to certain drugs or chemicals (Table 112.6), which is the cause in 50% of cases. Autoimmune disease, viral hepatitis, radiation, and pregnancy have also been associated with aplastic anemia. The aplastic state may extend to all cell lines and results from destruction by immune-stimulated lymphocytes or failure of the marrow stem cell. On occasion, only one cell line fails, as in RBC aplasia. This condition represents injury occurring at a later stage of cellular differentiation.

RBC, Red blood cell.
Clinical Features. Clinical presentation can be related to the anemia itself, such as fatigue. However, the more common presentation is from infections secondary to neutropenia or mucosal bleeding from the accompanying thrombocytopenia.

Diagnostic Testing. The diagnosis of aplastic anemia is suggested by the presence of low hemoglobin, low WBC count, and low platelets. Low reticulocyte count is also present, but the precise diagnosis necessitates bone marrow examination.

Management. General treatment of aplastic anemia includes removal of suspected marrow toxins from the environment, avoidance of aspirin, oral hygiene, and suppression of menses. Transfusions are given in life-threatening circumstances. Bone marrow or peripheral blood stem cell transplantation from a histocompatible sibling can cure bone marrow failure, with survival rates of 78% to 94%. However, only 30% of patients have suitably matched sibling donors to allow allogeneic transplantation. Immunosuppression with antithymocyte globulin, antilymphocyte globulin, and other cytotoxic chemotherapy is used in the majority of patients who are not stem cell transplantation candidates. Unrelated donors are preferred to avoid sensitization of the patient against the non-HLA antigens that are present in bone marrow from a family donor. The disease has a wide range of severity, and the overall 5-year survival rate is 30% to 40%. Even with supportive therapy, up to 80% of patients with severe aplastic anemia still die. Although difficult to find an immunologic match, bone marrow transplantation before blood product sensitization dates. Unrelated donors are preferred to avoid sensitization of the patient against the non-HLA antigens that are present in bone marrow from a family donor.

Clinical Features

The clinical signs and symptoms of hemolytic anemia are, in general, caused by either intravascular or extravascular processes, and this division assists in the differential diagnosis approach.

Intravascular hemolysis is usually associated with an acute process and has a dramatic appearance. Large numbers of RBCs may be lysed within the circulation. The pathologic process primarily involves the handling of released hemoglobin and a compensatory response to an acute decrease in oxygen-carrying capability. Free hemoglobin initially binds to haptoglobin and hemopexin. This complex is transported to the liver, converted to bilirubin, conjugated, and excreted. When this binding and transport system is overwhelmed, free hemoglobin may appear in the blood and tint it pink. In contrast, myoglobin is a small molecule that is rapidly cleared from serum. Examination of spun whole blood demonstrates clear serum in myoglobinemia, pink serum with free hemoglobin from intravascular hemolysis, and yellow serum from extravascular hemolysis with increased bilirubin production. In severe cases, the last mechanism may also result in free hemoglobin.

The clinical appearance of intravascular hemolysis may vary from mild chronic anemia, as seen in cases of mechanical hemolysis, to prostration, fever, abdominal and back pain, and mental changes, as seen with transfusion reactions. Jaundice, brown to red urine, and oliguria associated with acute renal failure induced by the hemoglobin complex can also occur.

The clinical picture of extravascular hemolysis is usually mild to moderate anemia, intermittent jaundice, and enlargement of the spleen. The signs and symptoms vary with the severity and chronicity of the hemolysis. Splenic blood flow slows as RBCs travel in the sinusoids close to the reticuloendothelial system, which is uniquely designed for removal of old or damaged cells. Primary splenic overactivity, antibody-mediated changes, or RBC membrane abnormalities may cause this normal splenic function to increase to a pathologic degree. Hemolysis may also occur within the bone marrow. Normal erythropoiesis is ineffective 10% to 20% of the time and can increase when abnormal RBCs are produced, as in thalassemia, megaloblastic anemia, or some hemolytic anemias. After hemoglobin is disassembled in the bone marrow, globin returns to the amino acid pool, iron is transported by transferring to the bone marrow or iron stores, and the pyrrole ring is converted to bilirubin. The unconjugated bilirubin circulates to the liver and is transformed and excreted in urine as conjugated bilirubin.

Differential Diagnoses

Hemolytic anemias may be classified as congenital or acquired, Coombs positive or Coombs negative, or caused by processes intrinsic or extrinsic to the cell membrane. The last method gives a useful differential diagnosis classification of hemolysis (Box 112.8).

Intrinsic Enzyme Defects. Eighty-five percent to 90% of the membrane-sustaining energy production of the erythrocyte is through the anaerobic glycolytic pathway. At least eight known enzyme deficiencies are associated with this pathway. The most common is pyruvate kinase deficiency, which is manifested with hemolytic jaundice and is usually diagnosed in infancy.

The remaining 10% to 15% of RBC glycolysis occurs by way of the hexose monophosphate shunt. This bypass mechanism occurs in the early stages of the glycolytic pathway and generates reduced nicotinamide adenine dinucleotide phosphate (NADPH),
The oxidant creates forms of activated oxygen, such as peroxide, which is important in maintaining reduced glutathione. Glutathione is essential in the protection of hemoglobin from oxidant injury. A deficiency of the first enzyme in this pathway, glucose-6-phosphate dehydrogenase (G6PD), occurs in 11% of African American men. In this form, the enzyme deteriorates with age, and older RBCs are subject to hemolysis by oxidant stress. G6PD deficiency is sex linked and has a wide range of severity. The most common form in African Americans is self-limited because as the bone marrow responds, younger cells with normal levels of G6PD predominate and handle the oxidant stress. The variants in Sicilians, Greeks, and Arabs can be particularly devastating. The clinical manifestation is usually an acute hemolytic episode that may be both intravascular and extravascular. It occurs 24 to 48 hours after the ingestion of an oxidant drug (Box 112.9) or after acute infections, such as viral hepatitis. The anemia induced by oxidant drugs is dose related. The older cells lyse at certain drug levels.

The oxidant creates forms of activated oxygen, such as peroxide, that either denature the hemoglobin or destroy cell membranes. The former process produces Heinz bodies, which are clumps of denatured hemoglobin found in RBCs that are removed by the spleen. The diagnosis is made by enzymatic screening for G6PD, but this test cannot be performed immediately after the hemolytic episode. A 3-week delay avoids a false-negative result caused by a predominance of young cells. Treatment includes volume and RBC support and avoidance of oxidant drugs.

**Intrinsic Membrane Abnormality.** These abnormalities are manifested in a number of ways. An altered shape is the main feature of autosomal dominant hereditary spherocytosis or elliptocytosis. The spleen sequesters these abnormal cells. Clinical sequelae range from compensated asymptomatic anemia to severe life-threatening acquired aplastic crises. The diagnosis is made by reviewing the family history, blood smear, and osmotic fragility testing. Splenectomy is the treatment of choice for patients requiring therapeutic intervention.

Paroxysmal nocturnal hemoglobinuria is a stem cell defect causing abnormal erythrocyte, neutrophil, and platelet sensitivity to complement. It is most often seen as chronic hemolysis, hemosiderinuria, leukopenia, and thrombocytopenia. The peripheral smear is normal and the direct Coombs test result is negative. Its major complication is thrombosis, with a predilection for the hepatic vein. Normal activation of complement with the use of sucrose or acid hemolysis (the Ham test) is diagnostic. Transfusion can be a life-threatening in patients with this disease because RBC lysis is caused by donor complement. Thus, only washed packed cells should be used.

**Intrinsic Hemoglobin Abnormality.** More than 350 types of abnormal hemoglobin have been documented. Problems that may be seen include unstable hemoglobins that appear as Heinz body–positive anemia, M hemoglobins that fix iron in its ferric or methemoglobin state, and hemoglobins with increased oxygen affinity that result in tissue hypoxia and erythrocytosis.

**Extrinsic Alloantibodies.** Alloantibodies are formed in response to foreign RBC antigens. In the case of the ABO system, these antibodies are preformed. One of the most important RBC wall antigens, ABO incompatibility resulting in donor cell destruction by the recipient’s alloantibodies can be a life-threatening reaction. These immunoglobulin M (IgM) antibodies can act as a hemolysin, both agglutinating RBCs, fixing complement, and consequently causing intravascular hemolysis.

The Rh system is another set of antigens on the RBC. Individuals do not have antibodies that correspond to antigens in the Rh system unless they have been sensitized by previous exposure to antigens that they lack. The antibodies produced are IgG in nature, and they accelerate extravascular destruction of RBCs by the spleen and liver. Most autoimmune antibodies are directed toward antigens in the Rh system.

**Extrinsic Autoantibodies.** Evaluation of autoimmune hemolysis is as complex as its origin. The major feature of autoimmune hemolysis is the production of an IgG or IgM antibody to an antigen present on the RBC membrane. IgM antibodies can agglutinate, fix complement, and act as intravascular hemolysins. IgG antibodies may fix complement to the cell but do not usually complete the hemolysis process. These IgG- or C3-labeled cells undergo accelerated extravascular destruction. The direct antiglobulin test is useful in revealing labeled cells.

Autoimmune hemolytic anemias are acquired disorders, with 40% to 50% being idiopathic. The remainder are associated with a number of diseases (Box 112.10). Classification of autoimmune hemolytic anemias is based on the optimal temperature at which the antibody reacts with the RBC membrane. Therefore, there are warm-reacting (>37°C) and cold-reacting (<37°C) antibodies.

### BOX 112.8

**Classification of Hemolytic Anemia**

**INTRINSIC**
- Enzyme defect
  - Pyruvate kinase deficiency
  - Glucose-6-phosphate dehydrogenase (G6PD) deficiency
- Membrane abnormality
  - Spherocytosis
  - Elliptocytosis
  - Paroxysmal nocturnal hemoglobinuria
  - Spur cell anemia
- Hemoglobin abnormality
  - Hemoglobinopathies
  - Thalassemias (anemias)
  - Unstable hemoglobin
  - Hemoglobin M

**EXTRINSIC**
- Immunologic
  - Alloantibodies
  - Autoantibodies
- Mechanical
  - Microangiopathic hemolytic anemia
  - Cardiovascular, such as prosthetic heart valve disease
- Environmental
  - Drugs
  - Toxins
  - Infections
  - Thermal
- Abnormal sequestrations, as in hypersplenism

### BOX 112.9

**Drugs Associated With Hemolysis in Glucose-6-Phosphate Dehydrogenase Deficiency**

Analgesics and antipyretics: acetanilid, aspirin, phenacetin
Antimalarials: Primaquine, quinacrine, quinine
Nitrofurans
Sulfa drugs: Sulfamethoxazole, sulfacetamide, sulfones
Miscellaneous: Naphthalene, fava beans, methylene blue, phenylhydrazine, nalidixic acid

When the diagnosis of hemolytic anemia is made, the classification is based on the optimal temperature at which the antibody reacts with the RBC membrane. Therefore, there are warm-reacting (>37°C) and cold-reacting (<37°C) antibodies.
Diseases Associated With Autoimmune Hemolytic Anemia

NEOPLASMS
Malignant: Chronic lymphocytic leukemia, lymphoma, myeloma, thymoma, chronic myeloid leukemia
Benign: Ovarian teratoma, dermoid cyst

COLLAGEN VASCULAR DISEASE
Systemic lupus erythematosus
Periarteritis nodosa
Rheumatoid arthritis

INFECTIONS
Mycoplasma
Syphilis
Malaria
Bartonella
Virus: Mononucleosis, hepatitis, influenza, coxsackievirus, cytomegalovirus

MISCELLANEOUS
Thyroid disorders, ulcerative colitis
Drug immune reactions

Drugs Associated With Immune Hemolytic Anemia

Hapten type with antibodies to the drug
- Complement-fixing antibody: Quinidine, quinine, phenacetin, ethacrynic acid, p-aminosalicylate, sulfa drugs, oral hypoglycemic agents
- Non–complement-fixing antibody: Penicillin dosages \( >20 \) million units/day

Autoimmune type with antibodies to the red blood cell (RBC)
- membrane: \( \delta \)-methylidopa, \( L \)-dopa, mafenamic acid, chlor Diazepoxide
- Cephalosporins at dosages \( >4 \) g/day may cause hemolysis by direct membrane injury

Warm-reacting antibodies are characterized by a higher incidence in younger patients (30 to 60 years old), predominance in women, variable complement fixation, and positive direct antiglobulin test result for IgG. Cold-reacting antibodies, or cold agglutinins, are seen predominantly in men and older patients (50 to 80 years old) and with IgM complement fixation. They may also be found in patients with infectious mononucleosis, Mycoplasma infection, and lymphoma. Hemolysis may be intravascular and extravascular, and the direct antiglobulin test result is positive for complement.

Drug-induced hemolytic anemia may be difficult to diagnose. The emergency clinician should know the drugs most often associated with this Coombs-positive phenomenon and realize that the result of this test is sometimes positive only in the drug’s presence. Common drugs and mechanisms of action are listed in Box 112.11.17

Extrinsic Mechanical Causes. Hemolysis may be caused by trauma to RBCs. The peripheral smear may demonstrate schizocytes or fragmented cells (Fig. 112.5). Microangiopathic hemolytic anemia, cardiac trauma, and exercise-induced hemoglobinemia are the most commonly encountered forms of traumatic hemolysis.

Microangiopathic hemolytic anemia is a form of microcirculatory fragmentation by threads of fibrin deposited in the arterioles. An underlying disease may be found in renal lesions, such as malignant hypertension and preeclampsia, vasculitis, thrombotic thrombocytopenic purpura, disseminated intravascular coagulation, and vascular anomalies. Signs and symptoms are those of intravascular hemolysis; treatment is directed at the cause.

Cardiac trauma to RBCs results from increased turbulence. It may be found in patients with prosthetic valves, traumatic arteriovenous fistula, aortic stenosis, and other left-sided heart lesions. Surgical correction may be necessary. Supportive therapy with iron is usually required.

March hemoglobinemia is a form of trauma caused by breaking of intravascular RBCs by repetitive pounding. Soldiers, marathon runners, and anyone with repetitive striking against a hard surface may incur this problem. Reassurance and a change in the patient’s pattern of activity are the recommended therapy.

Environmental Causes. Hemolysis may be seen in cases of severe burns, freshwater drowning, and hyperthermia. Toxic causes of hemolysis have been documented to be of animal origin, such as brown recluse spider and some snake bites; vegetable origin, such as castor beans and certain mushrooms; and mineral origin, such as copper. Certain infections are associated with hemolytic states, including malaria, Bartonella infection, and Clostridium sepsis.

Abnormal Sequestration. Hypersplenism may be caused by any disease that enlarges the spleen or stimulates the reticuloendothelial system. An unfortunate cycle can be set up in which the enlarged spleen traps more blood components and grows larger. It is usually seen as splenomegaly with pancytopenia and marrow hyperactivity. Chromium-labeled RBCs may demonstrate increased trapping in the spleen. Therapy for symptomatic or severe disease is splenectomy. Adults usually tolerate splenectomy well, but children should be approached conservatively because the risk of postsplenectomy life-threatening sepsis is increased significantly.

Diagnostic Testing
Once hemolysis is suspected, the history and laboratory tests have diagnostic precedence over physical examination. Important historical and physical examination points are listed in Box 112.12. Important diagnostic tests for hemolysis are provided in Box 112.13, and the interpretations of the laboratory evaluation of hemolytic anemias are included in Table 112.7. The blood smear
is often more diagnostic than bone marrow examination. The typical cell seen in intravascular hemolysis is the schizocyte (see Fig. 112.5). The classic cell of extravascular hemolysis is the spherocyte. It may be seen in congenital spherocytosis but more commonly indicates splenic activity against an antibody-coated RBC membrane. An increase in macrocytes reflects the presence of younger cells associated with reticulocytosis. The specific diagnosis may be made by a blood smear, as with sickled cells or Heinz bodies in G6PD deficiency.

Haptoglobin binds hemoglobin on a molecule-for-molecule basis. Its absence implies saturation and degradation after binding with hemoglobin and is an early finding in hemolysis. It has a normal range of 40 to 180 mg/mL, is decreased in hepatic failure, and increases as an acute-phase reactant. After haptoglobin is bound, hemoglobin binds with hemopexin, transferrin, and albumin before circulating in its free form. Plasma free hemoglobin levels are determined in suspected cases of intravascular hemolysis. The result is considered positive if the level is greater than 40 to 50 mg/dL. Hemoglobin is excreted by the kidney and may appear as a smoky red pigment that is orthotoluidine positive with no associated RBCs. Prussian blue–staining granules of hemosiderin may be found intracellularly in renal tubule cells excreted in urine during chronic hemolytic states.

**BOX 112.12**

Pertinent Factors in the History and Physical Examination for Hemolytic Anemia

**HISTORY**
- Alteration of color in urine or feces
- Association with drugs, cold, sleep
- Early or recent-onset anemia history with symptoms
- Ethnic background
- Family history of anemia or jaundice
- Drug or toxic exposure
- Disease states associated with hemolysis, such as systemic lupus erythematosus, renal failure, lymphoma, infectious mononucleosis, prostatic heart valve

**PHYSICAL EXAMINATION**
- Jaundice
- Hepatosplenomegaly
- Ulcerations, particularly in the lower extremities
- Enlarged lymph nodes

**BOX 112.13**

Diagnostic Tests for Hemolysis

- Peripheral blood smear
- Corrected reticulocyte index or reticulocyte production index
- Haptoglobin levels
- Plasma free and urinary hemoglobin
- Lactate dehydrogenase level
- Fractionated bilirubin level
- Direct and indirect Coombs test
- Red blood cell (RBC) membrane stability (osmotic fragility)

</table>

DIC, Disseminated intravascular coagulation; G6PD, glucose-6-phosphate dehydrogenase; HUS, hemolytic uremia syndrome; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura.
LDH is released when the RBC is broken down peripherally or in the marrow. It is elevated in hemolytic, thalassemic, sideroblastic, and megaloblastic anemia but may also be seen in cases of uremia, polycythemia vera, and erythroleukemia. Normal levels of LDH range from 95 to 200 IU and may be fractionated. In extravascular hemolysis, bilirubin is often delivered to the liver faster than the conjugating mechanism can handle it. Normal total levels are less than 1.5 mg/dL, with an indirect component less than 0.5 mg/dL. Unconjugated or indirect bilirubin may rise as high as 4 or 5 mg/dL even with normal liver function. Higher levels connote some degree of underlying hepatic insufficiency.

The direct antiglobulin (Coombs) test detects antibody or complement on human RBC membranes. It is an essential test in the evaluation of hemolysis. Approximately 90% of patients with autoimmune hemolytic anemia have a positive direct Coombs test result (warm agglutinin autoimmune hemolytic anemia). The indirect test measures antibody titers in serum (cold agglutinin autoimmune hemolytic anemia). The key to the direct antiglobulin test is the reagent, which contains an antihuman immunoglobulin G (IgG) produced in rabbits. This antihuman IgG in its broad-spectrum form reacts with the IgG, IgM, or C3 proteins that may coat RBCs. The reaction causes an agglutination of RBCs that is graded 0 to 4. Agglutinating properties depend on the size of the immunoglobulin. IgM is a large antibody form that can bridge the distance between cells, cause agglutination, and fix complement. The direct antiglobulin test is limited in diagnosis of IgM-mediated hemolysis. It is best in determining IgG or complement on the RBC surface. IgG is not large enough to cause agglutination, and the antihuman globulin attaches to RBC-bound IgG, which allows agglutination. C3 is detected in a similar manner. Both represent possible immunologic causes of hemolysis. This form of hemolysis is usually mediated extravascularly through the spleen, because IgG is a poor initiator of the complement system. The direct antiglobulin test evaluates the RBC surface for immunologic markers. The indirect test assumes that IgG or C3 is in the serum and tests for serum antibody activity against RBCs. Positive tests for immunologic markers do not correlate agglutination activity with the severity of hemolysis.

Management

In patients with newly diagnosed reticulocytopenia or severe hemolytic anemia, the emergency clinician may need to institute transfusion therapy. Compatible blood may be almost impossible to find because the antibody can react with almost all donors. The most compatible donor cells in terms of the ABO and Rh systems should be transfused with the knowledge that they will be no more compatible than the patient’s own blood cells. If emergency blood transfusion is required, type-specific or type O blood (Rh-positive for men; Rh-negative for women of childbearing age) is indicated, as well as prednisone or its equivalent in a dose of 1 mg/kg. Prednisone may produce an improvement in 60% of patients with warm antibody reactions. Splenectomy and immunosuppressive therapy are also effective. Cold agglutinin hemolytic anemia may be self-limited, as after infectious mononucleosis. Other forms respond well to cold avoidance, variably to immunosuppressive agents, but poorly to steroids and splenectomy. Death commonly results from uncontrolled hemolysis, the underlying primary disorder, and pulmonary embolism.

Sickle Cell Disease

Principles. Sickle cell disease is genetically determined. An abnormal allele at the gene loci for hemoglobin beta chains produces altered messenger RNA, which in turn results in replacement of glutamic acid by valine at the sixth position from the N-terminal end of the beta chain. The result is a sickled cell that is less deformable, an increase in the viscosity and sludging tendency of blood, and the sequestration of RBCs in the spleen and liver. The clinical complex of vaso-occlusive events, chronic hemolysis, thrombosis, and organ injury is derived from this pathologic process. Patients with sickle cell disease generally fall into two phenotypic groups: hemolysis phenotype and vaso-occlusion phenotype. These groups are not genetically determined, and it is still unknown why some people fall into one group versus the other. Patients prone to hemolysis typically do not have pain, stroke, or acute chest syndrome; instead, they typically have pulmonary hypertension and leg ulcers. Their hemoglobin tends to be very low, but their LDH is usually high. Patients with the vaso-occlusion phenotype typically have pain, acute chest syndrome, and stroke; they have a higher hemoglobin or high WBC level and lower LDH and indirect bilirubin concentrations.

The globin in hemoglobin is made up of two pairs of identical polypeptide globin chains. Each person has two non–sex-linked gene foci for the beta-globin chain, one from each parent. Normal individuals express six different types of hemoglobin from varying globin chain combinations: three embryonic hemoglobins, HbA (α2β2), HbA1 (α2δ2), and HbF (α2γ2). Embryonic hemoglobins are expressed only in utero, and after 6 months of age, HbA accounts for more than 95% of hemoglobin in a normal individual. The sickle syndromes result from mutations in the β-globin gene. Instead of HbA (α2β2), an abnormal hemoglobin Hbs is produced. Embryonic and fetal hemoglobins do not contain β-globin; thus, there are no clinical manifestations in early infancy. As their production declines, normal HbA (α2β2) cannot be produced, and symptoms develop.

In sickle cell trait (HbAS), the patient is heterozygous and only one parent contributes the abnormal S allele. In each cell, approximately 40% of the hemoglobin is HbS. Sickle disease (HbSS) is homozygous, and more than 85% of the hemoglobin is HbS. Because a parent may contribute alleles other than S, a wide number of variants can exist. Two clinically important S variants are sickle-cell–β-thalassemia and sickle cell–hemoglobin C disease. Therefore, not all hemoglobinopathies that cause sickling are HbS. In addition, HbSS is not limited to the African American population. Up to 10% of patients with various sickling disorders are not ethnically African American.

The sickle cell trait is found in 8% to 10% of African Americans. The diagnosis is usually made after sickle cell screening (Sickledex) and a characteristic result on hemoglobin electrophoresis. Most individuals with sickle cell trait are asymptomatic but can present with spontaneous hematuria, renal papillary necrosis, splenic infarction, venous thromboembolism, traumatic hyphema, exertional rhabdomyolysis, and exertional sudden death. Recent literature suggests that pregnancy in women with sickle cell trait is not associated with an increased risk of adverse events. In patients with sickle cell trait who have eye trauma, serial tonometry and observation are indicated to monitor for ocular complications.

Clinical Features. Sickle cell disease is characterized by two major clinical features, hemolysis and acute vaso-occlusive events. The hallmark manifestation of sickle cell disease and the most common reason for ED visits is the painful vaso-occlusive crisis. Preceding infection, cold exposure, and stress such as trauma are all potential precipitating factors. The painful crisis is believed to have its origin in tissue ischemia caused by increased viscosity, sludging, and microvascular obstruction as a result of irreversibly sickled cells. Sludging and vascular blockage cause stasis, deoxygenation, and local acidosis, which promotes continued sickling. The pain is commonly deep and aching and is most often found in the abdomen, chest, back, and extremities. The disease may mimic an acute abdomen (eg, cholecystitis), pulmonary embolus, renal colic, or other painful problems. A directed history that relates this pain pattern to previous sickling episodes, a careful repeated physical examination, and specific organ-related laboratory tests
can be used to differentiate “uncomplicated” crises from a more serious pathologic condition. Children may be seen more often with skeletal crises leading to bone deformities. In these cases, osteomyelitis and bone infarct needs to be differentiated.24

Neurologic complications can occur and include transient ischemic attacks, cerebral infarction, spinal cord infarction, vestibular hearing problems, and hearing loss. Neurologic complications occur in 25% of patients with sickle cell anemia by the time they are 45 years old; 13% demonstrate infarction or ischemia in the absence of symptoms.25 Transcranial Doppler study may be useful in identifying individuals with sickle cell disease who are at risk for stroke.26 The use of regular blood transfusions can reduce the risk of cerebrovascular events by 54%.27 In the setting of an acute stroke, exchange transfusion is recommended with the goals of hemoglobin S of less than 30% and a total hemoglobin level limited to 10 g/dL.27,28 Tissue plasminogen activator (tPA) should be considered in adult sickle cell disease patients with acute nonhemorrhagic strokes. The use of tPA in this setting is the same as for acute stroke without sickle cell disease.29

Acute chest syndrome is the most common pulmonary disease associated with sickle cell disease and one of the most common causes of death.30 It is a common cause of hospitalization in sickle cell disease, second only to vaso-occlusive crisis. Patients with acute chest syndrome have fever, cough, chest pain, dyspnea, and new infiltrates on the chest radiograph. The pathophysiologic mechanism of the syndrome is not well understood, but it may be a specific form of acute lung injury. The injury is postulated to be related to pulmonary microvascular sludging, infarction of pulmonary parenchyma, and bone marrow fat embolization from infarcted bone. Macrovascular pulmonary embolism and infection may also have a pathogenetic role. Although the causes of acute chest syndrome are uncertain, approximately 54% of the cases are associated with infection, including Mycoplasma and Chlamydia. The differential diagnosis includes pneumonia, pulmonary embolism, congestive heart failure, and adult respiratory distress syndrome. Management is primarily supportive and consists of hydration, analgesia, incentive spirometry, maintenance of adequate oxygenation and ventilation, and empirical antibiotics. Approximately 13% of patients will have respiratory failure severe enough to require mechanical ventilation. Antibiotic choice is similar to that for pneumonia in other populations. Exchange blood transfusions, as used in a similar fashion with acute stroke, are often used and have been associated with better gas exchange in acute chest syndrome. However, there are no randomized controlled studies demonstrating an improvement in outcome with the transfusions.

Although most of the diagnostic and therapeutic problems of sickle cell disease are related to vaso-occlusive crises, other serious complications should be anticipated. Sickle cell disease is a chronic hemolytic state with reasonably compensated hematocrit values in the 20% to 30% range and elevated reticulocyte counts. This compensated balance may be disrupted by a rare iron deficiency or, more commonly, by folate deficiency. A potentially life-threatening aplastic crisis may be seen as a result of suppression of erythropoesis by an acute postinfectious condition or folate deficiency. This aplastic condition is suspected when the hemoglobin level falls 2 g/dL or more from previous stable levels and the reticulocyte count remains low (<2%).

Finally, children may have an acute splenic sequestration syndrome. This syndrome involves acute splenic enlargement from increased intrasplenic sickling and obstruction. The child may demonstrate lassitude and be in shock. Each of these conditions may result in a rapidly falling RBC count and progressive symptoms of anemia. Patients with HbSS are also subject to all other causes of anemia, such as hemolysis from G6PD deficiency. An increased susceptibility to infection is well documented with HbSS.31

In infancy, pneumococcal sepsis and meningitis may lead to death. A WBC count and blood cultures should be performed on all febrile children with sickle cell anemia. HbSS patients who are younger than 2 years old and have associated temperatures of 39.5°C or higher and WBC counts greater than 20,000/mm³ should be given intravenous antibiotics immediately. Adults with fever require careful evaluation and laboratory assessment, including appropriate cultures. Early institution of appropriate antibiotics, such as ceftriaxone 1 to 2 g, adult dose, intravenously or intramuscularly, is necessary in patients with a discernible source of infection. In children and adults, infections with Staphylococcus and Pneumococcus species and Haemophilus influenzae are particularly common.32 An increased incidence of Salmonella osteomyelitis also occurs. The origin of this related immunologic deficiency is believed to be multifactorial, involving functional asplenia, poorly migrating neutrophils, and decreased opsonin production.

Major, chronic organ damage in patients with sickle cell anemia is common and is listed in Table 112.7. Based on clinical and autopsy findings, the leading causes of death in HbSS patients are acute chest syndrome (22%), sepsis (22%), and multiorgan failure (17%).33

In a patient with suspected sickle cell disease, inquiry should be made into the family history, previous pain episodes, and symptoms relative to chronic anemia, susceptibility to infection, and ischemic organ damage. Table 112.8 suggests an outline to follow for the physical examination.

### Differential Diagnoses

**Sickle Cell–β-Thalassemia.** Sickle cell–β-thalassemia disease is seen most commonly in people of Mediterranean descent. The severity of the disease is related to the concentration of HbS in RBCs and the decrease in MCHC. It should be

**Organ Damage Seen in Sickle Cell Disease**
considered in a patient with a low MCV and a positive response on sickle preparation. It is generally a milder form than homozygous HbSS but can be as severe as sickle cell disease. HbSC disease falls between HbSS and HbS-thalassemia in terms of severity. In addition to many of the complications of HbSS, HbSC disease has an increased incidence of eye hemorrhage and pregnancy complications and may cause splenomegaly. The peripheral smear demonstrates a combination of sickled cells and normocytic target cells.

Diagnostic Testing

Most patients, other than those with mild pain crisis, should have a complete blood count performed and compared with those of previous visits. A reticulocyte count is recommended whenever the patient’s hemoglobin level has decreased by 2 g/dL from baseline. In sickle cell disease, the typical absolute reticulocyte count is three or four times the upper limit of normal. A reticulocyte count 3% or lower than the patient’s usual value may suggest an aplastic crisis. A reticulocyte count greater than 12%, particularly if it is accompanied by numerous nucleated RBCs, may indicate rapid hemolysis. Unfortunately, no test is available that detects whether a patient is in a crisis and is based on clinical presentation. In undiagnosed cases, the peripheral smear may show sickled cells (Fig. 112.6), but the definitive diagnosis of sickle cell disease is confirmed by hemoglobin electrophoresis.

Management

The antisickling agent hydroxyurea reduces the frequency of painful crises in adults with a history of three or more crises annually. The beneficial effects of hydroxyurea in sickle cell disease are assumed to be due to induction of hemoglobin F, but additional mechanisms may be operative. Hydroxyurea can reduce the incidence of acute painful crisis, as well as increase survival. However, the effects of hydroxyurea can take weeks to be appreciated, and it is not routinely recommended for acute episodes.

Other agents, including clotrimazole, magnesium, 5-azatidine, erythropoietin, L-glutamine, and butyric acid, may have a future role. Bone marrow transplantation offers the only current cure for sickle cell disease and is associated with survival rates greater than 90% and disease-free survival rates of 80% to 90%. However, the role of bone marrow transplantation remains uncertain because of the inability to predict which patients will benefit, limited patient eligibility as a result of advanced pulmonary and neurologic vasculopathies, and concerns related to transplantation mortality and treatment-induced malignant neoplasms.

Current therapies, including rest, adequate nutrition, hydration, oxygenation, analgesia, transfusion, and therapy for infection, are directed toward symptomatic relief and attempts to stop the cycle of deoxygenated sickling and intravascular sludging. Most patients with sickle cell anemia are mildly dehydrated because of difficulty in concentrating urine. Fluid replacement can be oral or intravenous. Fluid replacement is not recommended unless signs of shock and a conservative approach for most patients recommends infusions of 5% dextrose in half-normal saline at a rate not to exceed 1.5 times maintenance. Although the use of supplemental oxygen may have some theoretical advantages in sickle cell disease, it has not been shown to reduce opioid use or hospitalization in patients that are not hypoxic.

Analgesia is a major benefit and essential early therapy for acute sickle cell crisis. Because a small subgroup of patients repeatedly and frequently seek care in the ED, caregivers may become understandably suspicious of needs and motivations. Many emergency clinicians caring for large populations of sickle cell patients have developed protocols to establish better physician-patient rapport and to lessen the chance of narcotic addiction and manipulation. The following is a protocol for severe pain in adults and children weighing more than 50 kg: patients are evaluated, treated with oxygen and hydration, and given intravenous morphine sulfate, 5 to 10 mg every 2 to 4 hours, or intravenous hydromorphone, 1.5 mg every 3 to 4 hours. For children weighing less than 50 kg, intravenous bolus doses of morphine sulfate, 0.1 to 0.15 mg/kg, can be given every 2 to 4 hours, or intravenous hydromorphone, 0.015 to 0.020 mg/kg, can be given every 3 to 4 hours. At 4 to 6 hours, the patient is allowed to decide whether inpatient or outpatient therapy is desired. Outpatient therapy includes 4 to 6 days of an effective oral analgesic. A 40-mg dose of oral morphine sulfate or equivalent is given 1 or 2 hours before the infusion is stopped. Such a protocol may bring uniformity to the patient’s expectations for care and the physician’s decisions about therapy and admission. Its major disadvantage has been a tendency to treat patients automatically rather than closely considering the potential acute complications of sickle cell disease. No standard pain management exists for sickle cell disease. A variety of analgesics (nonsteroidal antiinflammatory drugs, mixed opioid agonist-antagonists, and opioids), dosages, and timing intervals may be chosen. Because many sickle cell disease patients can have varying degrees of hepatic or renal dysfunction, acetaminophen and nonsteroidal antiinflammatory drugs should be used with caution. Because many patients with acute pain episodes are undertreated, the most important aspect of pain management is a consistent, thorough, and attentive approach that offers true pain relief.

Selected blood transfusion can decrease the chronic transfusion problems of antigen sensitization, iron overload, and hepatitis. Aplastic or splenic sequestration crises may necessitate transfusion. Whereas the overall goal of simple transfusion therapy for symptomatic anemia is a hemoglobin level no higher than 10 g/dL, asymptomatic patients should not be transfused, regardless of hemoglobin value.

Priapism is a painful complication of sickle cell disease and may lead to impotence. First-line therapy for priapism lasting longer than 2 hours is aspiration of blood from the corpus cavernosum and irrigation with an α-adrenergic agent (eg, phenylephrine). Urologic surgical management is reserved for patients who fail aspiration and irrigation. Exchange transfusions in the treatment of priapism is controversial but is currently not recommended.
Exchange transfusions are recommended for other complications, such as cerebrovascular accidents, in pregnancy and before major surgery. Acute stroke symptoms may be reversed and the frequency of recurrence decreased with a regulated 3- or 4-week transfusion program. The goal is to suppress reticulocytosis and to decrease the HbS level to less than 25%. Rarely, transfusions are given to control bone or visceral crises. This is not an ED procedure and is considered only after hematologic consultation.

Disposition

Many patients with painful crisis can be controlled in the ED and discharged with analgesics. Hospitalization may be warranted if pain cannot be controlled with two to three doses or if the patient is unable to take oral analgesics.

**POLYCYTHEMIA**

**Principles**

*Polycythemia* is a term commonly used for erythrocytosis (ie, increased number of RBCs). This disorder is seen occasionally in emergency medicine but rarely requires emergency intervention. An elevated RBC count, usually greater than the hematocrit, defines the disorder. It results in a low MCV, usually related to low serum iron and iron stores. Specific laboratory testing is discussed in the Differential Diagnosis section.

Erythropoiesis is controlled by the kidney-produced glycoprotein hormone erythropoietin. It is activated in the liver and regulates the committed erythropoietic stem cell. Its major stimulant is tissue hypoxia. Neoplastic dysfunction of bone marrow may also result in an elevated absolute RBC count.

The major complications of polycythemia are related to the increase in blood viscosity associated with increased RBC numbers. As the hematocrit rises past 60%, viscosity increases in an almost exponential manner, resulting in reduced tissue flow, thrombosis, and hemorrhage. This hazard is mitigated by an associated increase in blood volume and some viscosity-reducing vascular dilation.

**Clinical Features**

Symptoms may range from only mild headaches to a full-blown syndrome of hypervolemia (vertigo, dizziness, blurred vision, and headache), hyperviscosity (venous thrombosis), and platelet dysfunction (epistaxis, spontaneous bruising, and gastrointestinal bleeding).

On physical examination, the skin and mucous membrane manifest plethora, engorgement, and venous congestion (Fig. 112.7). Other systems to be examined include the fundus for venous congestion, the abdomen for evidence of splenomegaly, and the cardiopulmonary system for signs of congestive heart failure. Investigation for uterine, central nervous system, renal, and hepatic tumors should be sought, because these are associated with secondary polycythemia.

**Differential Diagnosis**

Polycythemia is classified as apparent, primary, or secondary (Box 112.14). Apparent polycythemia is a decrease in plasma volume, and RBC volume does not exceed the upper limit of normal. Found in overweight, hypertensive middle-aged men, “stress” polycythemia is the tendency for an elevated hematocrit possibly due to cigarette smoking with its associated increased carboxyhemoglobin level. The treatment includes weight loss and blood pressure control. The risk of vascular occlusive complications is minimal. The hematocrit is usually less than 60% and RBC mass measurements are normal.

Primary polycythemia vera is a myeloproliferative disorder found predominantly in middle-aged or older patients. Nonspecific symptoms are reported in up to 30% of patients and include headache, weakness, dizziness, excessive sweating, and pruritus. The most serious problems are thrombotic episodes (cerebrovascular accident, myocardial infarction, and deep venous thrombosis), bleeding, and bruising. Primary polycythemia vera involves all cell lines—hematopoietic stem, erythroid, granulocytic, and megakaryocytic. Elevated hemoglobin and RBC mass is present in virtually all, but a platelet count above 400,000/µL occurs in only 60% and a WBC count above 12,000/µL in only 40%. Bone marrow cellularity is increased in 90% of patients, and storage iron is absent from the marrow in 94%. The diagnostic criteria used by the Polycythemia Vera Study Group are listed in Box 112.15.

**Fig. 112.7.** Polycythemia vera. Facial plethora and conjunctival suffusion in a 40-year-old woman (hemoglobin, 19.5 g/dL). (From Hoffbrand AV, Pettite JE: Color atlas of clinical hematology, ed 3, London, 2000, Mosby, p 248.)

**BOX 112.14**

**Causes of Apparent and Secondary Polycythemia**

- Appropriately increased erythropoietin caused by tissue hypoxia
  - Congenital heart disease with a right-to-left shunt
  - Pulmonary disease (eg, bronchial-type chronic obstructive pulmonary disease)
  - Carboxyhemoglobinemia
  - High-altitude acclimatization
  - Decreased tissue oxygen release from hemoglobinopathies with high oxygen affinity
  - Inappropriate autonomous erythropoietin production
  - Renal origin: Carcinoma, hydrenephrosis, cyst
  - Other lesions: Uterine fibroids, hepatoma of adrenal origin, cerebellar hemangioma
  - Congenital overproduction
  - Pure or essential erythrocytosis
  - Acquired immunodeficiency syndrome (AIDS) and zidovudine treatment
Primary Polycythemia

Secondary polycythemia is classified according to the appropriate erythropoietin response to abnormal tissue oxygen levels. This group of disorders may be ruled out by normal measured arterial oxygen saturation. Second, inappropriate autonomous erythropoietin production is considered. This condition can be assessed with an erythropoietin assay. Because of a strong association with renal pathologic conditions, computed tomography should be used to evaluate a patient with a suspected inappropriate erythropoietin response. Most patients with secondary polycythemia have no central nervous system symptoms or splenomegaly. Because erythropoietin stimulates only the red cell pathway, these patients should have normal WBC and platelet counts.

Management

The emergency treatment of symptomatic polycythemia is phlebotomy. Usually, approximately 500 mL of blood is removed and replaced with a comparable amount of saline. No hemodynamic compromise should occur if this procedure is performed slowly. In true emergencies, up to 1 to 1.5 L of blood may be removed during a 24-hour period. The initial goal is to lower the hematocrit toward 60%. The final goal is a level less than 55%. Low-dose aspirin, 80 to 100 mg/day, has been shown to prevent thrombotic complications in patients with polycythemia vera and can be used in the acute and chronic treatment of this disorder.

Disposition

Selected patients with known polycythemia may be managed by serial outpatient phlebotomies. Any newly diagnosed or symptomatic patient should be considered for admission to the hospital for full evaluation.

### BOX 112.15

**Diagnostic Criteria for Polycythemia Vera**

**CATEGORY A**

- Increased RBC mass
  - In men: Hemoglobin >18.5 g/dL
  - In women: Hemoglobin >16.5 g/dL
- Normal arterial oxygen saturation (>92%)
- Splenomegaly

**CATEGORY B**

- Thrombocytosis: Platelets >400,000/mm³
- Leukocytosis: WBC count >12,000/mm³ (with no fever or infection)
- Leukocyte alkaline phosphatase score >100
- Vitamin B₁₂ >900 pg/mL, unbound vitamin B₁₂-binding capacity

*For polycythemia vera to be diagnosed, either all three criteria in category A or the first two criteria in category A along with any two criteria in category B needs to be present.

RBC, Red blood cell; WBC, white blood cell.

Although studies do not consistently demonstrate improvement in long-term survival, additional therapy may include hydroxyurea, busulfan, chlorambucil, interferon alfa, anagrelide, or radioactive phosphorus (³²P). The natural history of the disease is that it burns out after 15 to 20 years. However, myelofibrosis with myeloid metaplasia may develop. In 10% of cases, a rapid and poorly responsive acute leukemia develops. The 15-year survival for polycythemia vera is 65%. The most common causes of death are thrombosis (29%), hematologic malignant neoplasms (23%), nonhematologic malignant neoplasms (16%), hemorrhage, and myelofibrosis with myeloid metaplasia.

### Key Concepts

- Anemia is caused by three basic mechanisms: bleeding, destruction of RBCs, and decrease in production of RBCs.
- The use of RBC indices and a peripheral blood smear can help determine the mechanism of anemia.
- Anemia in the elderly often occurs as an exacerbation of preexisting comorbid diseases.
- Anemia of uncertain etiology should be thoroughly evaluated. If the patient has no adverse hemodynamic consequences, the evaluation can proceed on an outpatient basis or management initiated in an observation unit until the patient is stable and can be managed as an outpatient.
- Patients with sickle cell disease should be considered to have an acute pain crisis and treated appropriately until it is proved otherwise.
- Acute chest syndrome is one of the most common causes of death in sickle cell disease.
- Transfusion therapy is most useful in sickle cell disease associated with acute stroke (in children), acute chest syndrome, and splenic sequestration.
- Polycythemia is classified as apparent (eg, dehydration), primary (eg, myeloproliferative disorder), or secondary (eg, carcinoma or other conditions), and treatment is targeted at the cause.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
ChapteR 112. Anemia and Polycythemia

112.1. Anemia with an elevated mean corpuscular volume (MCV) is not typically seen with which of the following conditions?

A. Folate deficiency  
B. Hypothyroidism  
C. Iron deficiency  
D. Liver disease  
E. Vitamin B₁₂ deficiency

Answer: C. Iron deficiency. Anemia typically presents as a microcytic anemia. Liver disease may present with either a macrocytic anemia or a normocytic anemia reflecting an anemia caused by multiple mechanisms.

112.2. An elevated mean corpuscular hemoglobin concentration (MCHC) is expected in which of the following conditions?

A. Anemia of chronic disease  
B. Iron-deficiency anemia  
C. Sideroblastic anemia  
D. Spherocytosis  
E. Vitamin B₁₂ deficiency

Answer: D. The MCHC index is a measure of the concentration of hemoglobin. Low values represent hypochromia, whereas high values are noted only in patients with decreased cell membrane area relative to volume, such as spherocytosis.

112.3. A 31-year-old woman presents with complaints of easy fatigability and heavy regular menses. She is not pregnant and is otherwise healthy. Complete blood count shows the following:

- White blood cell (WBC) count: 7300 cells/mm³
- Platelet count: 453,000 cells/mm³
- Hemoglobin: 8.4 g/dL
- Hematocrit: 25%
- Mean corpuscular volume (MCV): 82 fl³ (81–100 fl³)
- Mean corpuscular hemoglobin concentration (MCHC): 29% (31% to 36%)

Physical examination is only remarkable for conjunctival pallor. Which of the following statements regarding this patient’s condition is true?

A. Hemoglobin rise from iron therapy begins in a week.
B. Parenteral iron therapy is indicated.

Answer: D. The patient’s condition is iron-deficiency anemia, likely due to chronic blood loss from menorrhagia. Iron therapy is indicated to correct the anemia and prevent further complications.
C. Reticulocytosis from iron therapy will be seen in 24 to 48 hours.
D. The normal MCV should prompt an in-depth anemia evaluation.
E. Transfusion is indicated.

Answer: A. Microcytic anemia, in cases of iron deficiency, occurs late because marrow and cytochrome iron sources must first be exhausted. The treatment for chronic iron-deficiency anemia is oral iron replacement, which in adults produces a reticulocytosis and hemoglobin rise in approximately 1 week. Parenteral iron therapy is almost never indicated. Transfusion is rarely required unless the blood loss is acute or comorbidities necessitate immediate improvement of blood oxygen-carrying capacity.

112.4. A 21-year-old man presents with easy fatigue and lack of energy. During a recent clinic visit, he was found to be anemic with a hemoglobin of 8 g/dL, mean corpuscular hemoglobin concentration (MCHC) of 25%, mean corpuscular volume (MCV) of 61 fL, and a peripheral smear remarkable for target cells and basophilic stippling. Serum iron levels were normal. What is the most likely explanation for his anemia?
A. Iron deficiency
B. Lead poisoning
C. Sideroblastic anemia
D. Thalassemia

Answer: E. Hypochromic, microcytic anemias with normal serum iron imply thalassemia (a defect in globin chain production). Both alpha- and beta-thalassemia show a hypochromic microcytic picture with target cells and basophilic stippling. The microcytosis is generally more severe than with iron-deficiency anemia. Sideroblastic anemia generally presents with elevated serum iron.

112.5. A 73-year-old woman presents with progressive fatigue. Her only past medical history is rheumatoid arthritis for which she takes methotrexate. She has no cardiopulmonary history and does not smoke. Physical examination is remarkable only for bilateral metacarpophalangeal, chronic swelling, and mild splenomegaly. Recent blood tests from the clinic are remarkable for a high normal serum iron, hemoglobin of 10 g/dL, and mean corpuscular volume (MCV) of 69 fL, with peripheral smear showing both microcytes and macrocytes. Which of the following is the most appropriate intervention?
A. A trial of pyridoxine
B. Hematology consultation for bone marrow biopsy
C. Hematology consultation for iron chelation
D. Send blood for vitamin B₁₂ and folate levels
E. Toxicology consultation for lead chelation

Answer: A. Sideroblastic anemia may be acquired or inherited. It is typically a refractory anemia in the elderly characterized by hypochromia and microcytosis but a dimorphic smear also showing normal cells and macrocytes. Some of these patients are pyridoxine deficient and may respond to a course of vitamin B₆. This anemia is a defect in porphyrin synthesis and is associated with rheumatoid arthritis, cancer, and infections. Lead poisoning is a subset. Elevated iron and ferritin levels are seen because the porphyrin defect does not allow iron incorporation and cells hemolysis in the bone marrow.

112.6. Which of the following statements regarding anemia of chronic disease is true?
A. A search for occult blood loss is indicated.
B. Hematocrits frequently fall to the 20% to 24% range.
C. Iron levels are always normal.
D. Iron therapy is beneficial.
E. It is a microcytic anemia.

Answer: B. Anemia of chronic disease (ACD) is a normocytic anemia most commonly associated with cancer, infection, and uremia. Hematocrit drops are generally modest, with levels seldom below 25% to 30%. An iron-deficiency anemia may often be superimposed, and a search for occult blood loss is indicated. It is characterized by low serum iron, low iron binding capacity, and increased ferritin. Bone marrow examination is often normal except for increased reticuloendothelial staining for iron, which cannot be mobilized. It is refractory to iron therapy.

112.7. A 43-year-old woman presents with difficulty walking and complaints of depression that have progressively worsened over several weeks. She has no past medical history, takes no medications, and does not drink alcohol or smoke. Physical examination is remarkable for clinical depression, a spastic gait, decreased extremity proprioception, and lower extremity hyporeflexia. What test should be obtained next in this patient’s evaluation?
A. Complete blood count with differential diagnosis and RBC indices
B. Lumbar puncture
C. Magnetic resonance imaging (MRI) of the spine
D. Serum potassium and calcium levels
E. Serum thyroid-stimulating hormone (TSH)

Answer: A. Vitamin B₁₂ deficiency presents classically with very low hemoglobin levels, a macrocytic picture, decreased proprioception and/or vibration, lower extremity spasticity/weakness with hyporeflexia, and often mental status changes, such as depression, forgetfulness, or even paranoia. Irritability and forgetfulness are also seen with folate deficiency.

112.8. A 43-year-old man presents with fatigue and dyspnea on exertion. He has no significant past history. Physical examination is remarkable for pale conjunctivae. Vital signs are heart rate, 108 beats per minute; blood pressure, 115/70 mm Hg; respiratory rate, 18 breaths per minute; temperature, 37° C; and O₂ saturation, 96% on room air. Laboratory examination is remarkable for the following:

White blood cell (WBC) count: 3200 cells/mm³
Hemoglobin: 7 g/dL
Hematocrit: 21%
Platelet count: 71,000 cells/mm³
Reticulocyte count: 0.9%

Which of the following tests will most likely lead to the diagnosis?
A. Drug/toxin exposure history
B. Fecal hemoccult test
C. Liver function tests
D. Serum creatinine
E. Urinalysis

Answer: A. Aplastic anemia typically presents as a normochromatic, normocytic anemia with a low reticulocyte count. Most cases
involve all cell lines. More than 50% of cases are due to drug or chemical exposures. See Table 112.6.

112.9. Which of the following conditions is associated with macrocytic anemia?
   A. Adrenal insufficiency
   B. Hypothyroidism
   C. Pituitary insufficiency
   D. Renal failure
   E. Tuberculosis

Answer: B. Hypothyroidism may be associated with macrocytic or normocytic indices. The latter is the typical case in anemia of chronic disease (ACD). All of the other choices may be associated with ACD and typically normocytic (occasionally microcytic) indices and low erythropoietin levels.
White Blood Cell Disorders

Timothy G. Janz | Alan A. Dupré

**CHAPTER 113**

**WHITE BLOOD CELL DISORDERS**

**Principles**

**Background and Importance**

The white blood cell (WBC) count and accompanying differential count are the most common laboratory tests ordered in the emergency department. Unfortunately, the WBC count has not proved to be a highly sensitive or specific test, and the absence of leukocytosis does not exclude the presence of significant disease. In evaluation of the bacterial infectious potential in febrile children, the WBC and differential counts have demonstrated limited usefulness. Other biomarkers, such as procalcitonin and C-reactive protein (CRP), may have more predictive value. Thus, the WBC test should be viewed as having limited screening value in the acute care setting because multiple agents and conditions can increase the WBC count. Although the WBC count may be nonspecific and nonsensitive, studies evaluating the WBC count for the diagnosis of abdominal pain have found it to be a useful in selecting patients for observation, and the differential count may provide helpful information. The absolute neutrophil count and a high band count may be more helpful than the total WBC count in identifying bacterial infection. Thus, it is essential that the basic physiology, pathophysiology, and clinical evaluation of WBCs be understood.

**Anatomy and Physiology**

The WBC series has three morphologically indistinguishable cell types: B cells (humoral immunity), T cells (cellular immunity), and null cells. Because lymphocytes can freely leave and return to the circulation, the storage pools are less well defined. Only 5% of the total lymphocytes in the body are in circulation. No marginal pool exists. Leukocytes primarily function extravascularly, and their function is closely integrated with the other types of white cells. WBCs reach their site of action through the circulation. The rate that new cells enter the circulation is usually in equilibrium with the rate of loss in tissues.

The granulocytic and lymphocytic series are the two WBC cell lines. The granulocytic series is primarily involved in phagocytic activity. Its origin is the pluripotential stem cells located in the bone marrow. A subset of these cells differentiates and matures into the phagocytic cell lines, which include neutrophils, monocytes, basophils, and eosinophils. Granulocytes are maintained in developmental and storage pools. The most important is the postmitotic storage pool for neutrophils, which represents 15 to 20 times the circulating population, and contains metamyelocytes, band neutrophils, and mature neutrophils (polymorphonuclear neutrophils). The pool can be drawn on as a ready reserve during rapid consumption of granulocytes. Circulating neutrophils are subdivided equally into the circulating neutrophil pool and the marginal pool, consisting of mature cells adherent to the blood vessel walls. The marginal pool can rapidly enter the circulating pool and cause a substantial increase, even doubling, of the WBC count. This involvement does not alter the maturity pattern of the differential count. The lymphocytic series matures in lymphoid tissues located in the bone marrow, thymus, spleen, lymph nodes, and elsewhere. They are involved in the immune response against foreign substances.

One unique problem in WBC disorders is the wide variability in normal values and the multiple factors influencing them. WBC counts are generally performed automatically by electrical impedance or optical diffraction techniques. Although differential counts are commonly performed by direct examination of 100 to 500 cells with the oil immersion lens of the microscope, automated techniques are becoming more popular. Normal values for the WBC count are listed in Table 113.1. The “normal” count is age dependent and may be shifted upward by exercise, gender (women), smoking, and pregnancy. Decreases in the total WBC count range by 1000 to 1200 cells/mm³ have been noted in the African American population. Laboratory errors may be due to improper sample preparation, nucleated RBCs, or platelet clumping. The blood smear differential count may also be influenced by small sample size, improper cell identification, and age group (children). Differential ranges are listed in Table 113.2. One common but easily corrected error in laboratory reporting is to give results in terms of the percentage of cell types. Absolute counts for each cell type are more accurate and useful in assessing the risk for infection.

**Pathophysiology**

Abnormal cell counts are due to changes in production, the marginal pool, or the rate of tissue destruction. Just as in anemia or platelet count abnormalities, the differential diagnosis of increased (leukocytosis) or decreased (leukopenia) WBC counts can be organized by processes altering production, destruction, loss, and sequestration.

Because of the wide range of normal values, all abnormal WBC counts should be interpreted in the context of the patient's condition. A careful history and physical examination, absolute cell counts, and review of the peripheral smear differential count are the starting points to determine the origins of quantitative WBC disorders.

Most cases of leukocytosis are caused by increases in the neutrophil or lymphocyte cell lines. Neutrophil leukocytosis (neutrophilia) is an absolute neutrophil count greater than 7500 cells/mm³ and is commonly associated with infection or inflammation (Box 113.1). Because increased neutrophil destruction is associated with both of these pathologic processes, the usual ratio of 1 band to 10 neutrophils increases. This increase is manifested as a “left shift” in the differential count and represents movement of immature neutrophils from the postmitotic pool into the circulation.

WBC counts can increase without a left shift or an increase in band forms by demarginating neutrophils from the vessel walls. It is often seen as a response to stress, exercise, or epinephrine. Severe stress can raise the WBC count to 18,000 to 20,000 cells/mm³.
Clinical Features

WBC disorders do not present with specific signs or symptoms but rather have clinical features associated with the underlying cause of the WBC disorder (eg, infection). The exception to this is hyperleukocytosis (WBC >100,000/mm³). Although most patients with hyperleukocytosis are febrile, the major organ systems involved are the lungs and the central nervous system (CNS). Pulmonary signs and symptoms include dyspnea and hypoxemia. CNS findings may include headache, tinnitus, visual changes, and altered mental status. Because cerebral hemorrhage and ischemia are not uncommon in hyperleukocytosis, signs and symptoms of an acute stroke are also possible.

Differential Diagnoses

Elevated WBC can be caused by primary WBC disorders (eg, myeloproliferative disorders, hereditary leukocytosis and congenital anomalies and leukemoid reaction, or secondary forms). Secondary forms are much more common (see Box 113.1).

Diagnostic Testing

Complete blood count (CBC) is the initial test, which usually identifies the WBC disorder. Presence of anemia, thrombocytopenia, or thrombocytosis on the CBC may also have diagnostic significance. As an example, the presence of an anemia, particularly hemolytic, and thrombocytopenia might suggest thrombotic thrombocytopenic purpura (TTP) or hemolytic uremia syndrome (HUS). Additional laboratory tests that may aid in the evaluation of a WBC disorder include a peripheral blood smear, sedimentation rate and CRP. In the setting of hyperleukocytosis, a chest radiograph and neurologic imaging, if CNS signs or symptoms are present, are also indicated.

Management

The management of WBC disorders is related to the underlying disease process associated with the disorder. Hyperleukocytosis, however, is a hematologic emergency and efforts should be made to lower the WBC as rapidly as possible. Reduction in the WBC can be achieved with chemotherapy, often hydroxyurea, and leukapheresis. Rapidly reducing the WBC with chemotherapy may induce the tumor lysis syndrome. The choice between chemotherapy and leukapheresis should be made in consultation with a hematologist. Because patients with pulmonary or CNS clinical features from hyperleukocytosis have a high mortality rate, leukapheresis is often the therapeutic modality of choice in this patient population.

Modified from Miale JB: Laboratory medicine: hematology, ed 6, St Louis, 1982, Mosby.
Disposition

Because WBC disorders are most commonly associated with an underlying disease process, the disposition of the patient depends on the type and severity of the underlying cause.

CHRONIC MYELOID LEUKEMIA

Principles

Anatomy and Physiology

Accounting for approximately 15% to 20% of adult leukemias, chronic myeloid leukemia (CML) is one of the myeloproliferative causes of neutrophilic leukocytosis. Although it is the least common of the major leukemias (60% acute, 31% chronic lymphocytic leukemia [CLL], and 15% CML), it should be considered in neutrophilia.

Pathophysiology

Patients with CML are usually older than 40 years old and have WBC counts greater than 50,000 cells/mm³. The differential count shows elevated polymorphonuclear neutrophils and metamyelocytes. Less often, the basophil and eosinophil counts are also increased. CML is a stem cell disorder in which the WBC count is elevated and the differential count is normal. Mature and intermediate granulocytes are overproduced. Platelets may also be increased, but RBC production is down, thereby resulting in anemia.

Clinical Features

Fatigue, anorexia, sweating, weight loss, and abdominal fullness are common symptoms associated with CML; however, up to 20% may be asymptomatic and the diagnosis suspected on routine blood count. Physical findings include pallor, sternal pain and tenderness, and splenomegaly (76% of patients; Fig. 113.1).

Differential Diagnoses

The differential diagnoses include a leukemoid reaction, lymphocytic leukocytosis, including CLL and ALL, which are discussed further later. A leukemoid reaction is a nonleukemic reactive granulocytic leukocytosis that resembles CML but has no associated Philadelphia chromosome (Ph¹), no absolute increase in basophils and eosinophils, and an increase in leukocyte alkaline phosphatase. It is difficult to distinguish from CML in the emergency department, and both need to be considered a potential diagnosis in granulocytic leukocytosis. WBC counts are usually greater than 50,000 cells/mm³. A leukemoid reaction may be seen in tuberculosis, Hodgkin’s disease, sepsis, and metastatic tumor, particularly bronchogenic, gastric, and renal carcinoma.

Diagnostic Testing

In the laboratory, decreased leukocyte alkaline phosphatase and increased vitamin B₁₂ levels are found, which helps differentiate CML from other causes of neutrophilia. The Ph¹ is associated with the disease.

Management

The chronic phase of CML is treated with an alkylating agent (eg, busulfan) or an antimetabolite (eg, hydroxyurea). Selected patients may benefit from bone marrow transplantation.

LYMPHOCYTIC LEUKOCYTOSIS

Principles

Anatomy and Physiology

Lymphocytic leukocytosis (lymphocytosis) is an age-dependent definition: 9000 cells/mm³, ages 1 to 6 years; 7000 cells/mm³, ages 7 to 16 years; and 4000 cells/mm³, adults. It is seen in a variety of disorders, primarily infections, and lymphoproliferative disease.
Pathophysiology

In the past, before therapy was available, *acute* and *chronic* were descriptive terms applied to lymphocytic neoplasms with respect to patient survival time. The terms *acute* and *chronic* are currently used to describe the cell maturity, rapidity of onset, and aggressiveness of therapy. CLL is primarily a B-cell disorder and is the most common type of leukemia in the population 50 years or older. Acute lymphocytic leukemia (ALL) is most commonly diagnosed in children younger than 10 years old. It is the most frequent malignant neoplasm in children younger than 15 years old.

Clinical Features

Patients with CLL initially complain of fatigue, weight loss, and increased susceptibility to infection, rashes, and easy bruising. The lymph nodes are nontender and smooth, and they may appear in only one or two areas. Splenic and hepatic enlargement occurs in more than 50% of patients.

The most common presenting symptoms of ALL are nonspecific and include fever, bleeding, bone pain, and lymphadenopathy. Although the most common symptoms associated with ALL are nonspecific, the persistence of any of these should prompt consideration of a malignancy. The potential for leukostasis increases in ALL when the blast count rises above 50,000 cells/mm³.

Diagnostic Testing

Laboratory support of the diagnosis of CLL is an absolute lymphocyte count greater than 5000 cells/mm³ in adults. Anemia, thrombocytopenia, and neutropenia are often found. Autoimmune hemolytic anemia, a positive direct antiglobulin test result, and other altered immune system problems are seen.

Management

Early therapy for CLL may be directed toward complications of anemia, thrombocytopenia, impaired or accentuated immune response, or enlarged lymph nodes or spleen. Leukostasis is seldom seen in CLL, but therapy is considered when the total count rises to higher than 200,000/mm³.13 The risk for a second incident cancer is higher in patient with CLL compared to the general public, particularly for melanoma.16

Oncologic therapy for ALL is based on clinical staging and includes chemotherapy or radiation therapy. Therapy has improved childhood survival; current 5-year overall survival rates are estimated at 78% to 85%. This response to treatment has not been found to the same degree in adults.17,18

Clinical Features

The physical signs of infection may be minimal in severe neutropenia because there are too few cells to generate a substantial inflammatory or purulent response.

The clinician should ask patients found to be neutropenic about their medication list, a prior history of neutropenia, a family history, and a review of recent infections. The review of systems focuses on bleeding problems, fatigue, sweats, weight loss, and autoimmune symptoms. The physical examination is directed toward sites of infection, lymphadenopathy, hepatosplenomegaly, and underlying disease.

Diagnostic Testing

In patients with severe neutropenia and fever, a full radiologic and direct examination of commonly involved areas, such as the chest and urine, should be performed, and sputum, urine, and blood culture specimens should be obtained.
Management

Basic isolation techniques, early admission, and consultation with another specialist are recommended. Specific therapies may be started after cultures and consultation are completed. A number of empirical antibiotic regimens are recommended for febrile patients with neutropenia. Human granulocyte colony-stimulating factor is often used in the setting of neutropenia, but it is best done in consultation with a hematologist.

Disposition

Patients with a clear reversible source or without significant clinical findings and mild to moderate levels of neutropenia may have outpatient follow-up arranged, preferably after discussion with their physician.

KEY CONCEPTS

- CLL is the most common leukemia in the elderly, and ALL is the most common leukemia in children.
- Splenomegaly is a common finding in leukemias.
- Leukostasis is usually not accompanied by clinical sequelae until the WBC is more than 500,000.
- Neutropenia plus a fever should be treated as a life-threatening infection until proven otherwise.
- Postinfection is the most common cause of neutropenia in children.
- WBC determination in the emergency department has poor sensitivity and specificity for any specific disease process.
- Inflammatory markers, absolute neutrophil count and bandemia may be more useful for identifying infection than the absolute WBC.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
provide helpful information. The absolute neutrophil count and selecting patients for observation, and the differential count may the diagnosis of abdominal pain have found it to be a useful in specific and nonsensitive, studies evaluating the WBC count for increase the WBC count. Although the WBC count may be non-.
	est should be viewed as having limited screening value in the usefulness. Other biomarkers, such as procalcitonin and C-reactive protein (CRP), may have more predictive value. Thus, the WBC of leukocytosis does not exclude the presence of significant disease.

All of the above statements are true. The WBC count (WBC) count, “because it will help determine whether the patient has a bacterial infection in the abdomen.” Which of the following statements best describes the use of WBC in the care of emergency patients? A. May be useful in selecting patients for observation B. The absolute neutrophil count and a bandemia may be more helpful than the total WBC count in identifying bacterial infection C. The WBC is nonspecific and nonsensitive and has little screening value in the ED D. All of the above Answer: D. All of the above statements are true. The WBC count and accompanying differential count are the most common laboratory tests ordered in the ED. Unfortunately, the WBC count has not proved to be a highly sensitive or specific test, and the absence of leukocytosis does not exclude the presence of significant disease. In evaluation of the bacterial infectious potential in febrile children, the WBC and differential counts have demonstrated limited usefulness. Other biomarkers, such as procalcitonin and C-reactive protein (CRP), may have more predictive value. Thus, the WBC test should be viewed as having limited screening value in the acute care setting because multiple agents and conditions can increase the WBC count. Although the WBC count may be nonspecific and nonsensitive, studies evaluating the WBC count for the diagnosis of abdominal pain have found it to be a useful in selecting patients for observation, and the differential count may provide helpful information. The absolute neutrophil count and a high band count may be more helpful than the total WBC count in identifying bacterial infection.

Which of the following can affect the “normal” white blood cell (WBC) count? A. Age and race B. Exercise C. Gender D. Smoking E. All of the above Answer: E. All of the above statements are true. One unique problem in WBC disorders is the wide variability in normal values and the multiple factors influencing them. Normal values for the WBC count are listed in Table 113.1. The “normal” count is age dependent and may be shifted upward by exercise, gender (women), smoking, and pregnancy. Decreases in the total WBC count range by 1000 to 1200 cells/mm³ have been noted in the African American population.

In evaluating a patient with severe neutropenia, which of the following is false? A. If the patient also has a fever, basic isolation techniques and specific therapies should be initiated after cultures are completed. B. If the patient also has a fever, urine and blood cultures should be obtained. C. The clinician should ask about their medication list, a history of neutropenia, a family history, and a review of recent infections. D. The physical signs of infection should be obvious because of the inflammatory response. E. The review of systems focuses on bleeding problems, fatigue, sweats, weight loss, and autoimmune symptoms. Answer: D. The physical signs of infection may be minimal in severe neutropenia because there are too few cells to generate a substantial inflammatory or purulent response.

A patient with a known history of chronic myeloid leukemia (CML) presents with shortness of breath. His white blood cell (WBC) count is 25,000 cells/mm. The etiology of his shortness of breath is least likely to be due to which of the following: A. Angina B. Heart failure C. Hyperleukocytosis resulting in pulmonary ventilation-perfusion abnormalities D. Renal failure and fluid overload E. Severe anemia
Answer: C. Hyperleukocytosis occurs, but the more mature, “less sticky” cells in CML do not usually cause problems unless the count exceeds 500,000 cells/mm³. A higher cell count may cause leukostasis and result in deafness, visual impairment, pulmonary ventilation-perfusion abnormalities, and priapism. Treatment involves hydration, leukapheresis, transfusion as necessary, allopurinol to prevent severe hyperuricemia, and specific chemotherapy. The need for urgent therapy in CML is usually related to hyperuricemia and renal injury or severe anemia and subsequent angina or heart failure.

113.5. When applied to lymphocytic neoplasms, the terms acute and chronic describe all of the following except:
   A. Aggressiveness of therapy
   B. Cell maturity
   C. Patient survival time
   D. Rapidity of onset

Answer: C. In the past, before therapy was available, acute and chronic were descriptive terms applied to lymphocytic neoplasms with respect to patient survival time. The terms acute and chronic are currently used to describe the cell maturity, rapidity of onset, and aggressiveness of therapy. Chronic lymphocytic leukemia (CLL) is primarily a B-cell disorder and is the most common type of leukemia in the population 50 years or older. Acute lymphocytic leukemia (ALL) is most commonly diagnosed in children younger than 10 years. It is the most frequent malignant neoplasm in children younger than 15 years of age.
Background and Importance

Hemostasis is the process of blood clot formation and represents a coordinated response to vessel injury. It requires an orchestrated response from platelets, the clotting cascade, blood vessel endothelium, and fibrinolysis. Thrombin-stimulated clot formation and plasmin-induced clot lysis are closely related and regulated. This dynamic process is often viewed in phases: formation of a platelet plug, propagation of the coagulation cascade, clot development, and fibrinolysis of the clot.

Most hemostatic abnormalities are acquired and result from drugs (eg, aspirin or warfarin [Coumadin]), from associated disease (eg, hepatic insufficiency), or from iatrogenic causes (eg, multiple transfusions).

Anatomy and Physiology

Vascular integrity is maintained by a lining of nonreactive overlapping endothelial cells supported by a basement membrane, connective tissue, and smooth muscle. These cells are important in maintaining a barrier to macromolecules and, when injured, in contributing to the metabolic response and local vasoconstriction. The endothelium contributes to both clot formation and regulation by producing substances, such as von Willebrand's factor (vWF), antithrombin III, heparin sulfate, prostacyclin, nitric oxide, and tissue factor pathway inhibitor.

Platelets have multiple roles in hemostasis. They are complex cytoplasmic fragments released from bone marrow megakaryocytes under the control of thrombopoietin. Platelets contain lysosomes, granules, a trilaminar plasma membrane, microtubules, and a canalicular system. Granules are an important component of hemostasis and contain over 300 metabolically active substances, including platelet factor 4, adhesive and aggregation glycoproteins, coagulation factors, and fibrinolytic inhibitors. Each participates in the process of coagulation and contributes to overall wound healing through the mediation of inflammation, immune response, and infection control. The platelet's role is termed primary hemostasis, and it is the initial defense against blood loss. A fibrin clot that incorporates coagulation factors usually reinforces a platelet plug. Platelet activity is summarized in Box 114.1. Any of the steps listed may be absent, altered, or inhibited by inherited or acquired disorders.

The coagulation pathway is a complex system of checks and balances that results in controlled formation of a fibrin clot. Coagulation factors have been given standard Roman numerals matching their order of discovery (Box 114.2). A simplified version of the coagulation pathway is presented in Figure 114.1. The clotting cascade is traditionally depicted as consisting of intrinsic and extrinsic pathways. The intrinsic pathway is initiated by exposure of blood to a negatively charged surface, such as a glass surface in the activated partial thromboplastin clotting time. The extrinsic pathway is activated by tissue factor exposed at the site of vessel injury or thromboplastin. Both pathways converge to activate factor X, which then activates prothrombin to thrombin. The primary physiologic event that initiates clotting is exposure of tissue factor at the injured vessel site. Tissue factor is a critical cofactor that is required for activation of factor VII. Activated factor VII activates factor X directly, as well as indirectly by activating factor IX.

Pathophysiology

Hemostasis depends on normal function and integration of the vascular, platelets, and coagulation pathways. Because of limited amounts of tissue factor and rapid inactivation by tissue factor pathway inhibitor, the extrinsic pathway initiates the clot process, but sustained generation of thrombin and clot formation depend on the intrinsic pathway through activation of factor IX by activated factor VII. Intrinsic, extrinsic, and common pathways function normally for hemostasis to occur, and each may be evaluated with laboratory tests. The clinically important groups of coagulation factors are shown in Box 114.3.

Thrombin-sensitive factors are activated by thrombin and may give rise to a bleeding disorder if defective synthesis occurs. Vitamin K–sensitive factors may also cause bleeding from defective synthesis, as occurs with liver disease and warfarin anticoagulants. Heparin in combination with antithrombin III affects the coagulation pathway at multiple sites.

All components of the coagulation reaction are necessary to prevent excessive bleeding. Hemostasis is a balance between the excessive bleeding state and thrombosis. Once coagulation is initiated, controls are necessary to prevent local or generalized thrombosis (Box 114.4).

CLINICAL FEATURES

History and Physical Examination

An outline of the history and physical examination is presented in Box 114.5. The history alone may be useful in differentiating between platelet and coagulation factor abnormalities. Platelet disorders are usually manifested as acquired petechiae, purpura, or mucosal bleeding and are more common in women. Platelet abnormalities can be caused by congenital disorders, but most are from acquired conditions. The bleeding source is usually a capillary with resultant cutaneous and mucosal petechiae or ecchymoses. Epistaxis, menorrhagia, and gastrointestinal bleeding are common initial symptoms. The bleeding is generally mild and occurs immediately after surgery or dental extractions. Petechiae and purpura may be noted on physical examination, and superficial ecchymoses may be found around a venipuncture site. The purpura associated with platelet disorders is typically asymptomatic and not palpable. This is in contrast to purpura associated with vasculitis, which can burn or itch and is palpable. Deep muscle hematomas and hemorrhages are not aspects of the clinical picture. The bleeding time is prolonged, and the platelet count may be low, normal, or high.
Coagulation problems are commonly congenital, characterized by delayed deep muscle or joint bleeding, and seen more often in men. Vascular disorders have signs and symptoms similar to those of thrombocytopenic states. The inherited forms are rare. Acquired forms are usually associated with connective tissue changes or endothelial damage.

**BOX 114.1**

**Role of Platelets in Hemostasis**

Adhesion to subendothelial connective tissue: Collagen, basement membrane, and noncollagenous microfibrils; serum factor VIII (von Willebrand’s factor [vWF]) permits this function; adhesion creates the initial bleeding arrest plug

Release of adenosine diphosphate, the primary mediator and amplifier of aggregation; release of thromboxane A, another aggregator and potent vasoconstrictor; release of calcium, serotonin, epinephrine, and trace thrombin

Platelet aggregation over the area of endothelial injury

Stabilization of the hemostatic plug by interaction with the coagulation system:
- Platelet factor 3, a phospholipid that helps accelerate certain steps in the coagulation system
- Platelet factor 4, a protein that neutralizes heparin
- Pathway initiation and acceleration by thrombin production
- Possible secretion of active forms of coagulation proteins
- Stimulation of limiting reactions of platelet activity

**Coagulation Factors**

I. Fibrinogens
II. Prothrombin
III. Tissue thromboplastin
IV. Calcium
V. Labile factor (proaccelerin)
VI. Not assigned
VII. Proconvertin
VIII. Antihemophilic A factor
IX. Antihemophilic B factor (plasma thromboplastin component, Christmas factor)
X. Stuart-Prower factor
XI. Plasma thromboplastin antecedent
XII. Hageman factor (contact factor)
XIII. Fibrin-stabilizing factor

**Thrombocytopenia**

Thrombocytopenia from decreased bone marrow production is usually caused by the effects of chemotherapeutic drugs, myelophthisic disease, or direct bone marrow effects of agents, such as alcohol or thiazides. Splenic sequestration is a rare cause of thrombocytopenia but is seen primarily with hypersplenism resulting from hematologic malignant disease, portal hypertension, or disorders involving increased splenic red blood cell (RBC) count.

**Fig. 114.1.** Coagulation pathway.
Clinical Evaluation of a Bleeding Patient

**BOX 114.3**
Clinically Important Groups of Coagulation Factors

Thrombin-sensitive factors contributing to the metabolic response and local vasoconstriction: I, V, VIII, XIII

Vitamin K-sensitive factors: II, VII, IX, X

Sites of heparin activity: IIa, IXa, Xa (major site), Xla, platelet factor 3

**BOX 114.4**
Normal Controls of Coagulation

Removal and dilution of activated clotting factors through blood flow, which also mechanically opposes growth of the hemostatic plug

Alteration of platelet activity by endothelium-generated nitric oxide and prostacyclin

Removal of activated coagulation components by the reticuloendothelial system

Regulation of the clotting cascade by antithrombin III, protein C, protein S, and tissue factor pathway inhibitor

Activation of the fibrinolytic system

**BOX 114.5**
Clinical Evaluation of a Bleeding Patient

**HISTORY**

Nature of bleeding
- Petechiae
- Purpura
- Ecchymosis
- Significant bleeding episodes

Sites of bleeding
- Skin
- Mucosa: Oral or nasal
- Muscle
- Gastrointestinal
- Genitourinary
- Joints

Patterns of bleeding
- Recent onset or lifelong
- Frequency and severity
- Spontaneous or after injury

Challenges to hemostasis
- Tooth extraction
- Operative procedures
- Association with medication, particularly aspirin
- Medications
- Associated diseases
- Uremia
- Liver disease
- Infection
- Malignant neoplasm
- Previous transfusion
- Family history

**PHYSICAL EXAMINATION**

Vital signs

Skin: Nature of bleeding, signs of liver disease

Mucosa: Oral or nasal

Lymphadenopathy

Abdomen: Liver size and shape, splenomegaly

Joints: Signs of previous bleeding

Other sites of blood loss: Pelvic, rectal, urinary tract

destruction, such as hereditary spherocytosis or autoimmune hemolytic anemia. Thrombocytopenia resulting from increased destruction has several clinical important etiologies.

**Immune Thrombocytopenia.** Thrombocytopenia associated with increased peripheral destruction of platelets and shortened platelet survival caused by an antiplatelet antibody is seen in a number of diseases. Collagen vascular diseases, particularly systemic lupus erythematosus, may cause an antiplatelet antibody-related platelet decrease. Similar associations have been noted with leukemia and lymphoma, particularly lymphocytic lymphoma. All evaluations of suggested immune thrombocytopenia should include a complete blood count, peripheral smear, antinuclear antibody test, and bone marrow examination.

A number of drugs have been associated with thrombocytopenia of immunologic origin. Quinine and quinidine are common offenders that affect platelets through an “innocent bystander” mechanism. The platelet is coated with a drug-antibody complex, complement is fixed, and intravascular platelet lysis occurs. Because of its relatively high frequency, heparin is an important cause of drug-induced thrombocytopenia in hospitalized patients. Platelets are activated by the formation of an immunoglobulin G (IgG)–heparin complex.

Low–molecular-weight heparin (LMWH) may be associated with less thrombocytopenia than standard, unfractionated heparin (UFH); however, both forms of heparin demonstrate cross-reactivity. Heparin-induced thrombocytopenia (HIT) is a serious immune-mediated side effect associated with heparin.

The overall risk for HIT is around 1.2% for all patients receiving UFH or LMWH with certain surgical and medical illnesses conferring higher risk. It usually occurs 5 to 7 days after the initiation of heparin treatment. Thrombus develops in approximately half the patients with HIT. The thrombotic complications can lead to limb loss in up to 20% and death in as many as 30%. The diagnosis is suggested with absolute thrombocytopenia or a greater than 50% reduction in platelets after the initiation of heparin. The most specific diagnostic tests for HIT are serotonin release assays, heparin-induced platelet aggregation assays, and solid-phase immunoassays. Platelet-associated IgG levels are commonly elevated, but this finding is less specific or sensitive than the other diagnostic tests. More concerning to the emergency clinician is delayed-onset HIT. This form of HIT occurs a median of 14 days after the initiation of heparin, but it can occur up to 40 days after heparin is started. Arterial or venous thrombosis typically develops in patients with HIT. The administration of heparin results in the generation of antibodies to the heparin and platelet factor 4 complex, which is removed from the circulation, and results in thrombocytopenia. However, this complex also results in the generation of microparticles that have procoagulant properties and thrombus formation.

Digoxin, sulfonamides, phenytoin, and aspirin are other drugs that may be associated with a thrombocytopenia. The patient has usually ingested the medication within 24 hours. An idiopathic thrombocytopenic purpura (ITP) type of syndrome has also been reported in intravenous cocaine users. Clinical trials with platelet glycoprotein IIb/IIIa antagonists suggest that intravenous glycoprotein IIb/IIIa inhibitors may confer an increased risk for associated thrombocytopenia, independent of heparin therapy.

The platelet count may fall below 10,000/mm³ and be complicated by serious bleeding. Laboratory testing may confirm the presence of antibody, especially with the use of quinine and quinidine. After the drug is stopped, platelet counts improve slowly during a period of 3 to 7 days. A short course of corticosteroid therapy, such as prednisone in a dose of 1 mg/kg with rapid tapering, may facilitate recovery.

Postinfectious immune thrombocytopenia is usually associated with viral diseases, such as rubella, rubella, and varicella.
Although many cases associated with sepsis have a mechanical origin, some immune mechanisms have been demonstrated.

Post-transfusion thrombocytopenia is a rare disorder that causes a precipitous fall in platelets approximately 1 week after the transfusion. In 90% of cases, its origin is linked to the 98% of the population carrying a PLAI antigen on platelets. Despite the fact that 2% of blood recipients are mismatched with respect to this antigen, it is fortunately a rare occurrence. When a PLAI antigen-negative patient receives a platelet transfusion, the platelets with attached PLAI antibodies provoke an anamnestic response, but the actual mechanism of platelet destruction remains unknown. The platelet count often falls precipitously below 10,000/mm³, with a significant risk for major bleeding. Intracranial hemorrhage occurs in approximately 10% of such cases. Patients are usually middle-aged women with a history of pregnancy who may have been previously sensitized to the PLAI antigen during pregnancy. Plasma exchange therapy is an effective intervention.

**Idiopathic Thrombocytopenic Purpura.** Autoimmune ITP is considered after other causes of thrombocytopenia have been excluded. ITP is associated with an IgG antiplatelet antibody that has proved difficult to detect. The two clinically important forms are acute and chronic.

The acute form of ITP is seen most often in children 2 to 6 years old. A viral prodrome commonly occurs within 3 weeks of its onset. The platelet count decreases, usually to less than 20,000/mm³. The course is self-limited, with a greater than 90% rate of spontaneous remission. Morbidity and mortality rates are low, although full recovery may take several weeks. Treatment of acute ITP is supportive. Steroids and intravenous immune globulin therapy are reserved for patients with active bleeding.

The chronic form of ITP is primarily an adult disease found three times more often in women than in men. The onset of chronic ITP is insidious, without a prodrome, and it is manifested as easy bruising, prolonged menses, and mucosal bleeding. The patient may have petechiae or purpura, and platelet counts are usually less than 20%. The hemolysis may cause jaundice or pallor, and the blood smear characteristically contains numerous schistocytes and fragmented RBCs. Neurologic symptoms include stroke, seizures, paresthesias, altered levels of consciousness, and coma, all of which characteristically fluctuate in severity. The renal component varies from hematuria and proteinuria to acute renal failure. Fever is present in 90% of patients.

**Dilutional Thrombocytopenia.** Dilutional thrombocytopenia occurs in cases of massive transfusion, exchange transfusion, or extracorporeal circulation. Volume replacement with stored blood is platelet poor because platelets have a life span of only 9 days. The number of transfusions directly correlates with the degree of thrombocytopenia. Current transfusion practice is to monitor platelet counts for every 10 units of RBCs and to transfuse once the platelet count approaches 50,000/mm³.

**Thrombocytopenia.** Knowledge of abnormal platelet function as a clinical disorder has grown rapidly in recent years. The drug-induced form may be one of the most commonly seen causes, especially in intensive care unit (ICU) patients. Defects may occur at any level of platelet function, including adhesion, release, and aggregation.

**Adhesion Defects.** The representative adhesion disorder is von Willebrand’s disease (vWD), which is a factor VIII problem more than a platelet deficiency. Platelets are normal in terms of their morphologic condition, number, release, and aggregation. The abnormal adhesion results not from the platelet but from an endothelium-based plasma deficiency of a factor VIII component (vWF) that permits platelet adhesion.

**Release Defects.** Release defects include “storage pool” syndromes in which release is normal but amounts of adenosine diphosphate, calcium, and serotonin are decreased. Release defects may be congenital or acquired, such as in systemic lupus erythematosus, alcoholism, or lymphoma. Drugs induce the most common release problem. Aspirin and related drugs block the enzyme cyclooxygenase, which participates in thromboxane A₂ formation. Decreased release of thromboxane A₂ results in decreased aggregation and less local vasoconstriction. Both may increase the risk of bleeding. Testing for this risk may be performed with post-aspirin bleeding time. Aspirin is unique in that it permanently poisons this reaction for the life of the platelet in doses of only 300 to 600 mg. Indomethacin affects function only while it is present in the circulation. A similar problem may occur in patients with uremia or dysproteinemia and as a rare inherited form.
**Aggregation Defects.** Primary aggregation defects are associated with the rare recessive trait thrombasthenia. This platelet membrane abnormality may be detected by the lack of clot retraction during a 2-hour clot retraction test.

**Thrombocytosis**

Thrombocytosis is a platelet count higher than 600,000/mm³; Box 114.6 presents the list of potential causes. It is often caused by infection or iron deficiency, in which case it is not generally associated with platelet-associated complications. The primary or autonomous state may be associated with bleeding or thrombosis. It is often an associated finding in patients with polycythemia vera, myelofibrosis, or chronic myelogenous leukemia, and in children with Kawasaki disease. Suggested autonomous thrombocytosis requires a full hematologic evaluation.

**Disorders of the Coagulation Pathway**

The coagulation system accomplishes secondary hemostasis through a complex enzymatic cascade. The clinically significant disorders have a number of characteristic features that help differentiate them from platelet disorders (Box 114.7).

The prothrombin time (PT) and partial thromboplastin time (PTT) are the basic laboratory diagnostic tools for the evaluation of coagulation disorders and can be used to organize the approach to their diagnosis.

**BOX 114.6**

**Differential Diagnosis of Platelet Disorders**

**THROMBOCYTOPATHY**

Adhesion defects such as von Willebrand’s disease (vWD)

Release defects: Acquired and drug related

Aggregation defects, such as in thrombasthenia

**THROMBOCYTOPHENIA**

Decreased production

- Decreased megakaryocytes secondary to drugs, toxins, or infection
- Normal megakaryocytes with megaloblastic hematoipoiesis or hereditary origin
- Platelet pooling and splenic sequestration

Increased destruction

- Immunologic
  - Related to collagen vascular disease, lymphoma, leukemia
  - Drug related
  - Infection
  - Post-transfusion
  - Idiopathic (autoimmune) thrombocytopenic purpura
- Mechanical
  - Disseminated intravascular coagulation (DIC)
  - Thrombotic thrombocytopenic purpura (TTP)
  - Hemolytic-uremic syndrome (HUS)
- Vasculitis

Dilutional secondary to massive blood transfusion

**THROMBOCYTOSIS**

Autonomous (primary thrombocytosis)

Reactive (secondary thrombocytosis)

Iron deficiency

Infection or inflammation

Trauma

Nonhematologic malignant disease

Postsplenectomy

Rebound from alcohol, cytotoxic drug therapy, folate or vitamin B₁₂ deficiency

**Abnormal Prothrombin Time and Other Test Results Normal**

An elevated PT reflects an extrinsic pathway abnormality mediated through deficiency of factor VII. The hereditary form is caused by a rare autosomal recessive gene. The acquired form is commonly seen and may be a result of vitamin K deficiency, warfarin use, or liver disease. Because factor VII has the shortest half-life (3 to 5 hours) of the coagulation factors, it is the first to manifest a deficiency when its active form is underproduced. The PT is a sensitive gauge of hepatic function and the efficacy of warfarin administration. International normalized ratios (INRs) calculate the prothrombin ratio raised to the power of an international sensitivity index for specific thromboplastin reagents. It is recommended with most warfarin therapy that the INR be maintained between 2.0 and 3.0, except in the setting of cardiac valvular disease, in which the target INR is 2.5 to 3.5.

**Abnormal Partial Thromboplastin Time and Other Test Results Normal**

Two groups of inherited disorders manifest as an isolated elevation in the PTT. The first group involves deficiencies of the contact factors (eg, XII [Hageman factor]), prekallikrein (Fletcher factor), and high-molecular-weight kininogen. They cause a benign disorder in which the PTT is elevated but the patient has no bleeding diathesis. These deficiencies exist as isolated laboratory abnormalities, and thus they should not be invoked as a cause of the patient’s bleeding problem. They may be specifically assayed when a precise diagnosis is necessary.

The second group causes significant bleeding problems resulting from deficiencies of factors within the intrinsic coagulation system. They are the most common inherited abnormalities of the entire clotting system. Deficiencies of factors VIII, IX, and XI account for 99% of inherited bleeding disorders. Patients with active life-threatening bleeding who are thought to have a congenital bleeding disorder can be supported with fresh frozen plasma, 15 mL/kg, while diagnostic studies are being performed.

In a patient with a prolonged PTT and a lifelong history of bleeding, the most important test is assay of factor VIII and factor IX. This test measures the ability of the patient’s plasma to correct the prolonged PTT of plasma deficient in factor VIII. This ability is compared with that of normal plasma, and the result is given as a percentage of normal. The test measures the procoagulant activity of factor VIII but does not discriminate between abnormal activity resulting from abnormal factor VIII and low levels of normal factor VIII. The two forms of this deficiency are hemorrhhia A and vWD.

**BOX 114.7**

**Features of Coagulation Disorders Which Differentiate From Platelet Disorders**

The bleeding source is often an intramuscular or deep soft tissue hematoma from small arterioles.

The congenital form of the disease occurs predominantly in men, often as a sex-linked inheritance.

Bleeding may occur after surgery or trauma but is delayed in onset up to 72 hours.

Epistaxis, menorrhagia, and gastrointestinal sources of bleeding are rare, whereas hematuria and hemorrhhia are common in severe cases.

The bleeding time is normal except in patients with von Willebrand’s disease (vWD).
Hemophilia A. Hemophilia A is caused by a variant form of factor VIII that is present in normal levels but lacks a clot-promoting property. Factor VIII circulates in plasma in very low concentration and is normally bound to vWF. The source of factor VIII production is uncertain, but the liver is thought to be a significant source because hemophilia A can be corrected by liver transplantation. The incidence of hemophilia A is 60 to 80 persons per million population. Of known cases, 70% have been found to have a sex-linked recessive nature; that is, the disease is carried on the X chromosome at location Xq28. The remaining 25% to 30% of cases of the disease are believed to result from a spontaneous genetic abnormality. The familial form has a remarkable consistency of severity from generation to generation, although the degree of severity has considerable variation. This severity may be directly related to the level of factor VIII coagulant (factor VIII:C) activity. Cases with less than 1% activity are severe, with a tendency toward spontaneous bleeding. Cases with 1% to 5% activity are moderate, with rare spontaneous bleeding but increased problems with surgery or trauma. Cases with 5% to 10% activity and above are considered mild, with little risk of spontaneous bleeding but still with hazards after trauma and surgery. A number of hemophiliacs may have activity above 10% but have few problems under normal conditions. The PTT may lack sensitivity for this group because it is significantly prolonged only at factor VIII:C levels less than 35% to 40%.

The disease is seen as a disorder of secondary hemostasis with a characteristic pattern of bleeding. Bleeding can occur anywhere, but deep muscles, joints, the urinary tract, and intracranial sites are the most common. Recurrent hemorrhage and progressive joint destruction are major causes of morbidity in hemophilia. Intracranial bleeding is the major cause of death in all age groups of hemophiliacs. Mucosal bleeding, such as epistaxis and oral bleeding, or menorrhagia is rare unless the disease is associated with vWD or platelet inhibition, such as with aspirin use. Gastrointestinal bleeding is rare unless peptic ulcer disease is also present. Trauma is a common initiator of bleeding in all grades of severity. This potential hazard should be viewed expectantly in all hemophiliacs because late bleeding may occur, usually by 8 hours but potentially up to 1 to 5 days and, rarely, even longer after traumatic injury.

von Willebrand’s Disease. To understand vWD, it is helpful to review the nomenclature used to refer to factor VIII in some centers. Factor VIII has at least three activities. First is its antihemophilic, or coagulant, activity, VIII:C. All references to factor VIII in this chapter thus far have been to this activity. A second activity supports platelet adhesion and in vitro aggregation with the antibiotic ristocetin; it is called von Willebrand’s factor activity, or VIII:vWF. A third component reacts with rabbit antibodies to factor VIII; it is termed the factor VIII antigen, or VIII:Ag, and relates to the measured plasma level rather than to the activity of factor VIII. The antigen and cofactor activity for platelet function are structurally related. vWD has both decreased factor VIII:Ag levels and decreased VIII:C activity secondary to underproduction. The patient’s platelets are normal in number, morphologic condition, and other functions, but in the absence of circulating factor VIII:vWF, their adhering properties are diminished. vWD is the most common hereditary bleeding disorder, with an estimated prevalence of 1%. The disease occurs in 5 to 10 persons per million population as an autosomal dominant trait with a variable penetrance pattern. A rare X-linked inheritance has been described.

Manifestations of vWD are usually milder and less crippling than those of hemophilia. The factor VIII:C level is in the 6% to 50% range. Bleeding sites are predominantly mucosal (eg, epistaxis) and cutaneous. Hemarthroses are rare, but menorrhagia and gastrointestinal bleeding are common. Laboratory differential diagnosis from hemophilia A includes abnormal bleeding time, decreased level of factor VIII:Ag, and abnormal platelet aggregation with ristocetin.

Hemophilia B (Christmas Disease). Hemophilia B is a deficiency of factor IX activity. Its genetic pattern and clinical findings are indistinguishable from those of hemophilia A, but its incidence is only a fifth that of hemophilia A. Factor IX is a vitamin K–dependent glycoprotein. Its deficiency is diagnosed by a factor IX assay, usually after the factor VIII:C assay is found to be normal.

Miscellaneous Coagulation Disorders

A number of other disorders may be caused by a deficiency in the common coagulation pathway. An altered fibrinogen level or abnormal function is a relatively common cause. Patients with this deficiency also have an abnormal thrombin time. The inherited forms are rare. The acquired forms have been related to fibrin-blocking substances and hypofibrinogenemia, which are found most often in cases of disseminated intravascular coagulation (DIC) and dysfibrinogenemia associated with macroglobulinemia, multiple myeloma, and hepatoma. In the context of emergency medicine, fibrinogen’s most important role relates to its activity in DIC.

The other components of the common pathway (factors II, V, and X) have rare inherited deficiencies. The acquired forms are far more common and relate to vitamin K deficiency (decreased factor II, VII, IX, and X activity), warfarin use (same factors as with vitamin K deficiency), hepatic insufficiency (potentially all factors except VIII), and massive transfusion of stored blood (low in factors V and VIII and platelets).

Disseminated Intravascular Coagulation. DIC is a relatively common acquired coagulopathy. Its ubiquitous nature, multiple origins, and potentially devastating sequelae, balanced by an effective mode of therapy, make early diagnosis of this hemostologic process critical. It is most often encountered in the critical care setting. Hemostasis is achieved by a fine balance between procoagulants and inhibitors, and thrombus formation and lysis. The balance may be disturbed by pathologic processes that result in an out-of-control coagulation and fibrinolytic cascade within the systemic circulation. The abnormal clotting sequence observed in DIC is shown in Box 114.8.

The clinical consequence of these processes is the life-threatening combination of a bleeding diathesis from loss of platelets and clotting factors, fibrinolysis, and fibrin degradation product interference; small-vessel obstruction and tissue ischemia.
from fibrin deposition; and RBC injury and anemia from fibrin deposition. The condition needs to be considered in any patient in whom purpura, a bleeding tendency, and signs of organ injury, particularly of the central nervous system and kidney, develop. This broad description is further confused clinically by the variable acuteness and intensity of intravascular clotting, the effectiveness of fibrinolysis, and other systemic manifestations of the initiating disease. The clinical diagnosis of DIC is confirmed by laboratory tests (Table 114.1).

Two conditions that may simulate DIC are severe liver disease and primary fibrinolysis. Liver disease of this severity is usually manifested by clinical jaundice and splenomegaly. Primary fibrinolysis is a rare disorder that affects fibrinogen and fibrin but generally leaves the coagulation components (platelets, factor V, and factor VIII) in the low-normal range. Additional laboratory tests can be used to confirm the diagnosis of primary fibrinolysis, but these are not typically obtained in the emergency department (ED) and are best ordered in conjunction with a hematologist.

**DIFFERENTIAL DIAGNOSIS**

When a bleeding disorder is diagnosed or suggested, the assessment initially includes stabilization, which may necessitate volume, RBC, and coagulation factor replacement. If the disorder is known, clinical complications associated with its underlying pathophysiologic condition needs to be considered. If the disorder is unknown, a rapid differential diagnosis must be made. The differential diagnosis of vascular disorders is listed in Box 114.9. The differential diagnosis of platelet disorders is listed in Box 114.6.

**DIAGNOSTIC TESTING**

A definitive diagnosis depends on laboratory evaluation. Tests pertinent to the ED are discussed in the following sections and listed in Box 114.10.
Bleeding Time and Platelet Function Assay

Historically, bleeding time was considered the best test to determine both vascular integrity and platelet function. However, this test is insensitive in identifying medication related platelet dysfunction, vWD, and in predicting surgical bleeding. Some institutions have replaced the traditional bleeding time with a platelet function analyzer instrument, which is more convenient, with similar clinical value. A normal time is 8 minutes, a time of 8 to 10 minutes is borderline, and a time longer than 10 minutes is typically abnormal. The platelet function assay has been found to be highly sensitive in detecting moderate to severe vWD, medication related platelet dysfunction, and severe platelet function disorders. Although less sensitive to more mild disease, the platelet function assay is useful in detecting platelet pathology relevant to the emergency clinician. Because of the high incidence of drug-induced platelet dysfunction, ask the patient about medications, particularly aspirin and other antiplatelet medications (eg, clopidogrel). Platelet function testing is independent of the coagulation pathways.

Prothrombin Time

The PT tests the factors of the extrinsic and common pathways. The patient's anticoagulated plasma is combined with calcium and tissue factor prepared from rabbit or human brain tissue. Sensitivity to factor deficiencies depends on the source of the tissue factor. The PT detects deficiencies in fibrinogen, prothrombin (factor II), factor V, factor VII, and factor X. Results are reported in seconds or as the prothrombin ratio. To generate the prothrombin ratio, the time in seconds of the sample is given over the time of a normal control, for example, 12.5/11.5. Results are also usually reported as the INR, which compensates for differences in sensitivity of various thromboplastin reagents to the effects of warfarin. The factor V level is helpful in monitoring the use of coumarin anticoagulants, and the time may be prolonged in patients with liver disease and other abnormalities of vitamin K–sensitive factors.

Partial Thromboplastin Time

The PTT tests the components of the intrinsic and common pathways, that is, essentially all factors but VII and XIII in the entire clotting cascade. In this test, a phospholipid source and a contact-activating agent (kaolin) are added to anticoagulated citrate plasma. After an incubation period that allows factor XII to become activated, calcium is added and the clotting time is recorded. A normal control sample is run simultaneously. Normal ranges may vary by laboratory. The average time is 25 to 29 seconds. The sensitivity of the test varies from factor to factor, but factor levels usually are less than 40% before the PTT is prolonged. The test may be altered by clotting factor inhibitors of external origin (eg, heparin) or internal origin (eg, anti-VIII antibody). Inappropriately high values may occur if the plasma is too turbid or icteric. The activated PTT is most sensitive to abnormalities in the sequence of the coagulation cascade that precedes activation of factor X.

Anti-Xa Assay

The anti-Xa assay is a chromogenic assay which is becoming increasingly available to emergency clinicians for monitoring of unfractionated and LMWH levels and drug quantification of rivaroxaban and apixaban. When monitoring heparin levels, the test should ideally be performed 3 to 4 hours after medication administration for peak level monitoring. Because this test is not subject to the variability of the PTT, this test has become more attractive as costs have declined in recent years. The test is considered the reference standard for measurement of in vivo heparin activity and represents the only reliable means of quantifying rivaroxaban and apixaban drug levels.

Fibrinogen

Fibrinogen is present in sufficient concentration to be measured directly. Because it is the final coagulation substrate, its level reflects the balance between production and consumption. It may be decreased by low production, as in severe liver disease, or by overconsumption, as in DIC. Low levels and altered function increase the PT, PTT, and thrombin clotting time. Because fibrinogen is an acute-phase reactant, certain conditions, including malignant disease, sepsis, inflammation, and pregnancy, may alter the test result.

Thrombin Time

Measurement of the thrombin clotting time bypasses the intrinsic and extrinsic pathways by directly converting fibrinogen to fibrin. It is a useful screening test for both qualitative and quantitative abnormalities of fibrinogen and inhibitors, such as heparin and fibrin split products. The test is also a valuable means to measure drug activity of direct-thrombin inhibitors, such as dabigatran.

Clot Solubility

The result of clot solubility testing may be the only abnormality in disorders involving factor XIII deficiency. A washed clot is incubated in acetic acid or urea. If the fibrin clot is not properly cross-linked by factor XIII, it dissolves.

Factor Level Assays

Factor levels are determined either by bioassay, in which the ability of the sample of plasma to normalize controlled substrate-deficient plasma is evaluated, or by immunologic assay. Inhibitor screening tests reveal antibodies in plasma that prolong the normal plasma clotting time when mixed.

MANAGEMENT

Out-of-Hospital Treatment

The out-of-hospital treatment of hemostatic disorders presents no special concerns beyond potential identification and bleeding control. Local pressure and volume repletion are the mainstays of therapy for blood loss. Coagulopathies may complicate any medical or traumatic problem, and coagulopathy can rapidly develop in critically ill patients. Patients who do not respond quickly to the usual measures of hemostasis in the field should be considered to have a potential bleeding disorder.

Platelet Disorders

Platelet Transfusions. Most platelet function disorders are not treated by platelet transfusion, because its efficacy is questionable and alloimmunization may occur. Platelet transfusions are commonly indicated for primary bone marrow disorders (eg, aplastic anemia or acute leukemia). Assessment of the risk for spontaneous bleeding by platelet counts is an imprecise science. Less mature platelets associated with peripheral consumption or sequestration are less likely to allow spontaneous hemorrhage than are those associated with primary bone marrow involvement. An estimate of functionality is combined with the platelet count for a better predictor of primary hemostasis potential. At counts below 40,000 to 50,000/mm³, a variable degree of risk exists,
especially associated with trauma, ulcers, or invasive procedures. At counts higher than 50,000/mm³, hemorrhage caused by platelet deficiency is unlikely. Spontaneous bleeding in the absence of surgery, trauma, or other risk factors may occur in patients with platelet counts below 5000 to 10,000/mm³, and prophylactic platelet infusions should be reserved for this level of thrombocytopenia. Transfusion of platelets in this setting should be initiated in consultation with a hematologist.

**Medication-Induced Thrombocytopenia**

As mentioned earlier, digoxin, sulfonamides, phenytoin, aspirin, glycoprotein IIB/IIIa antagonists, quinine and quinidine, and aspirin are drugs that may be associated with a thrombocytopenia. After the drug is stopped, the platelet count improves slowly during a period of 3 to 7 days. A short course of corticosteroid therapy, such as prednisone in a dose of 1 mg/kg with rapid tapering, may facilitate recovery.1

**Post-Transfusion Thrombocytopenia**

For the rare disorder that causes post-transfusion thrombocytopenia, plasma exchange therapy is an effective intervention.2

**Heparin-Induced Thrombocytopenia**

Treatment of thrombotic complications in patients with HIT involves the use of direct thrombin inhibitors (lepirudin, argatroban), factor Xa inhibitors (fondaparinux), or heparinoids (danaparoid).3

**Idiopathic Thrombocytopenic Purpura**

Treatment of acute ITP is supportive. Steroids and intravenous immune globulin therapy are reserved for patients with active bleeding.4 However, with chronic ITP, associated diseases, such as lymphoma and systemic lupus erythematosus, needs to be ruled out before the diagnosis of ITP can be made. Quantitative laboratory tests of antiplatelet antibody may differentiate between patients who will favorably respond to therapy and those who will not. Hospitalization is recommended during the initial evaluation, because the differential diagnosis is complex and the risk of bleeding is significant. Management includes stopping all nonessential drugs, particularly those that inhibit platelet function (eg, aspirin). The initial treatment of chronic ITP is typically corticosteroids (prednisone, 1 mg/kg per day). Intravenous immune globulin and anti-D immunoglobulin, in conjunction with steroids, have also been used as first-line therapy. However, these therapies are best used after consultation with a hematologist. Splenectomy, monoclonal antibody therapy, and immunosuppressives are considered in steroid-failure cases.5 A thrombopoietin-receptor agonist, eltrombopag, has recently been shown in a well-designed trial to increase platelet counts in patients with relapsed or refractory ITP and thus might have a future role.6 Platelet transfusions are used only to control life-threatening bleeding because of increased antiplatelet antibody titers and short-lived hemostatic effect. Although it is rare, life-threatening bleeding is treated with platelet transfusions, intravenous immune globulin (0.7 g/kg), and methylprednisolone (15 mg/kg intravenously).7 Although recombinant factor VIIa has been used in ITP to stop bleeding, concern for thrombosis limits its use when safer alternatives are available.

**Thrombotic Thrombocytopenic Purpura**

Before the availability of plasma exchange, TTP followed a progressive and fatal course, with 90% mortality rate 1 to 3 months after diagnosis. Therapy has included corticosteroids, splenectomy, anticoagulation, exchange transfusion, and dextran. However, plasma exchange with fresh frozen plasma (plasmapheresis) is the standard treatment, often with adjunctive rituximab.14 This therapy has reduced the mortality to as low as 6.4%.22 In addition to plasma exchange, initial therapy may also include steroids (such as, prednisone) and antiplatelet agents (such as, aspirin and dipyridamole). If TTP is suspected in the ED, a hematologist should be consulted before any therapy is initiated. With the exception of life-threatening bleeding, platelet transfusion is avoided because platelets may cause additional thrombi in the microcirculation.

**Hemophilia A**

**Management of Hemophilia A**

Comprehensive management of hemophilia involves a team effort of physicians, specialized nurses, physical therapists, social workers, the patient, and the patient’s family. The therapeutic responsibility of the emergency clinician consists of three areas: (1) preparation for and identification of the problem, initial evaluation, and admission of newly diagnosed hemophilia patients; (2) replacement therapy for bleeding episodes; and (3) anticipation of potential life threats and admission of patients with known hemophilia A for observation in selected circumstances. At one time, treatment of hemophilia-associated bleeding was a relatively common emergency medicine activity, but since 1975, hemophilia home therapy has increasingly been instituted. Therefore, many hemophiliacs now come to the ED only with complicated problems or trauma-related difficulties, and most are knowledgeable about their disease.

**Preparation.** ED management of hemophilia is best accomplished with advanced planning that includes protocols developed with a hematologist for the administration of factor VIII. Emergency clinicians should have rapid access to hemophilia patients’ relevant information, including primary physician and hematologist, diagnosis, factor VIII activity level, blood type, presence of antihemophilic factor antibodies, and time of last hospitalization. This may be accomplished through an electronic medical record system or a maintained file of known hemophilia patients.

**Replacement Therapy.** The accepted therapy for hemophilia A is factor VIII replacement with cryoprecipitate or factor VIII:C concentrates. These concentrates are exposed to heat treatment or solvent-detergent mixtures to decrease transmission of hepatitis B virus, hepatitis C virus, and HIV. Factor VIII is also produced by recombinant DNA techniques and is considered to be the replacement product of choice.18 Recombinant-derived factor VIII is comparable to plasma-derived factor VIII in terms of characteristics and control of bleeding. Factor VIII:C concentrates are commonly used in severe hemophilia and for home therapy. Cryoprecipitate is the cold precipitable protein fraction derived from fresh frozen plasma thawed at 1° to 6°C. It was once the mainstay of hemophilia A therapy and may be used when noninfected factor VIII concentrates are not available.10

Before 1985, plasma-derived replacement therapies posed risk for transmission of hepatitis C virus, hepatitis B virus, and HIV. However, with the current methods of donor screening, antiviral techniques, and safety testing and with the availability of recombinant clotting factors, the risk of viral transmission is extremely low.

Therapy for a bleeding episode includes a number of considerations: the circumstances in which factor VIII is given, the dosage, the timing of maintenance, the duration of the dosage, the presence of antibodies, and the means of gauging effectiveness. As a general rule, 1 U/kg of factor VIII will increase the circulating
2. In emergency therapy, the present level of factor VIII is assumed to be zero.
3. One unit is the activity of the coagulation factor present in 1 mL of normal human plasma.
4. Because the half-life of factor VIII is 8 to 12 hours, the desired level is maintained by giving half the initial dose every 8 to 12 hours.
5. Cryoprecipitate is assumed to have 80 to 100 U of factor VIII:C per bag; factor VIII:C concentrates list the units per bottle on the label.

Most importantly, the emergency clinician should act and institute early therapy for patients who say that they are bleeding. The response to therapy can be monitored by clinical improvement, a decreasing PTT, and, optimally, serial factor VIII:C activity levels. The lack of a response to factor VIII administration should raise the possibility of circulating antibodies. All hemophiliacs should be screened for the development of these antihemophilic factor antibodies when they are given in-hospital therapy or if their condition becomes refractory to home therapy. The 7% to 20% of patients in whom these IgG antibodies develop usually have a severe deficiency necessitating multiple factor VIII transfusions. The treatment may be complex, and hospitalization is necessary. A variety of therapies have been considered, but current

factor VIII level by 2%. The dose of factor VIII needed is the desired percentage increase in factor VIII activity \( \times 0.5 \times \) the weight in kilograms. The typical percentage factor VIII activity goals are 25% to 40% for minor bleeding or trauma, greater than 50% for moderate bleeding, and 80% to 100% for serious, life-threatening bleeding or trauma. Tables 114.2 and 114.3 include guidelines for the recommended treatment in a variety of circumstances. The standard calculation dosage of factor VIII (antihemophilic factor) is as follows:

1. Patient’s plasma volume (50 mL/kg × weight in kg) \( \times (\text{desired level of factor VIII } \% ) - (\text{present level of factor VIII } \%) = \) number of units for initial dose.
treatments of choice include bypassing agents and immune tolerance induction. Recombinant factor VIIa used in hemophilia complicated by alloantibody inhibitors has been shown to stop bleeding in 93% of cases. Serious or intractable bleeding may be improved in some nonhemophilic patients with the use of recombinant factor VIIa. However, no improvement in survival has been proved, and the incidence of thromboembolism may be increased. Until more data are available, the role of recombinant factor VIIa in settings outside of congenital coagulation disorders remains to be determined. Acquired IgG antihemophilic factor antibodies may exist in nonhemophilic patients. They can occur in the postpartum period; as immunologic reactions to penicillin or phenytoin; and in association with systemic lupus erythematosus, rheumatoid arthritis, or inflammatory bowel disease. The diagnosis is made by the occurrence of an acquired hemophilia-like syndrome with positive antibody titers in the appropriate setting.

Desmopressin acetate has been shown to increase levels of factors VIII:C and VIII:Ag in patients with hemophilia A and in some with vWD. It is given intravenously at 0.3 µg/kg per dose. Benefits are primarily noted in patients with mild to moderate disease, and the effects of a single dose last for 4 to 6 hours. Use of desmopressin in the ED is probably best reserved for patients who have been successfully treated with it in the past or in consultation with the patient’s hematologist.

**Prophylaxis.** The anticipation of delayed bleeding in patients with hemophilia may necessitate admission and observation for a variety of trauma-related injuries. Candidates for prophylactic admission are patients with deep lacerations; those with soft tissue injuries in areas where the pressure from a developing hematoma could be destructive, such as in the eye, mouth, neck, back, and spinal column; and patients with a history of major trauma forces without injury. Head trauma is potentially life-threatening to hemophiliacs, and central nervous system bleeding is the major cause of death for patients in all age groups. Studies find a 3% to 13% risk of intracranial hemorrhage. In patients with severe disease who sustain head trauma, patients are significantly less likely to suffer delayed intracranial bleeding if given replacement therapy within 6 hours. Patients who sustain head trauma but who have normal computed tomography scans should have factor VIII therapy initiated to greater than 50% activity level. All hemophiliacs with head trauma should be considered for admission with early hematology consultation.

Gene therapy represents a potential development in the treatment of hemophilia. With the goal of increasing expression of functional factor VIII, the possibility exists for either a partial or complete cure of hemophilia through various gene therapy approaches. Early studies are encouraging, but significant challenges still prevent gene therapy from being an approved treatment at this time. However, genetic testing and counseling are currently available.

**Hemophilia B**

The replacement schedule for factor IX is similar to that for hemophilia A, but a purified factor IX concentrate or recombinant factor IX preparation is used. The plasma prothrombin complex (factors II, VII, IX, and X) and fresh frozen plasma are also useful, but they pose a higher risk of viral transmission and venous or arterial thrombosis. The maintenance dosage schedule is increased to every 24 hours because of the longer half-life of factor IX. Clinical concerns and treatment strategies associated with hemophilia A also apply to hemophilia B.

Similar to hemophilia A, gene therapy in hemophilia B has advanced beyond hemophilia A due to a relative simplicity and smaller gene size. Multiple recent clinical trials using gene therapy to treat hemophilia B have been initiated.

**von Willebrand’s Disease**

In patients with severe vWD, replacement therapy with factor VIII in the form of intermediate purity factor VIII concentrate is the method of choice. The initial dose is 50 IU/kg followed by 20 to 40 IU/kg every 12 hours to keep vWF levels at 50% or to control bleeding. A unique response to the transfusion of plasma components in patients with vWD is the stimulation of a progressive increase in VIII:C activity that lasts 12 to 40 hours. After the initial dose, fewer units are necessary, and longer dosage schedules may be followed by a clinical response and a combination of factor VIII:C activity and serial bleeding times. Cryoprecipitate is no longer recommended because of the risk of viral transmission.

Desmopressin is of benefit in patients with mild to moderately severe vWD. Because most patients fall within this category, it is a preferred treatment given the low cost and risk associated with this medication. Adjunctive antifibrinolytic agents, such as tranexamic acid, have also shown benefit in vWD. In extreme circumstances without alternatives, fresh frozen plasma may be used. A factor VIII concentrate (Humate-P) has also demonstrated sufficient VIII:vWF to treat the disease.

**Medication-Induced Bleeding**

Excessive anticoagulation from warfarin occurs from a number of causes, including interactions between warfarin and other drugs or foods and accompanying diseases that interfere with the absorption or metabolism of warfarin. Management of excessive anticoagulation from warfarin depends on the degree of elevation of the INR and if bleeding accompanies the excessive anticoagulated state. If the INR is below 5.0 and not accompanied with bleeding, treatment consists of withholding of additional warfarin. If the INR is between 5.0 and 9.0 without bleeding, in addition to withholding of additional warfarin, 1.0 to 2.5 mg of oral vitamin K therapy is recommended. Patients presenting with an INR above 9.0 but not bleeding are treated with 5 mg of oral vitamin K. Patients presenting with an elevated INR and bleeding require 10 mg of vitamin K and the administration of fresh frozen plasma or prothrombin complex concentrates. Vitamin K can be administered orally, intravenously, or subcutaneously. Oral dosing is superior to other routes of administration, and subcutaneous injection is the least desirable method of administration. In cases of excessive anticoagulation with warfarin that are accompanied by serious or life-threatening bleeding, vitamin K is often administered intravenously. Vitamin K given intravenously should be administered as an infusion during 20 to 30 minutes and not given as a bolus injection.

Bleeding from heparin therapy is less of an issue in the ED but still can be a problem (eg, patient coming from a dialysis center). In addition to discontinuation of the heparin, the administration of protamine sulfate can urgently reverse the effects of heparin. The full neutralizing effect of UFH is achieved with 1 mg of protamine for every 100 units of heparin. Protamine can also be used to reverse the effects of LMWH; however, it does not completely abolish the anticoagulant effects as it does with UFH. When it is used for bleeding caused by LMWH, the dose of protamine is 1 mg for every 1 mg of LMWH. Because rapid injection of protamine results in hypotension, the recommended rate of administration is no more than 50 mg during 10 minutes. Recombinant factor VIIa may be considered in resistant forms of bleeding from anticoagulation; however, it is not a substitute for vitamin K, protamine, or blood product transfusions.

Over the past several years, new target-specific oral anticoagulants (TSOACs) have been gaining popularity. The first to gain
U.S. Food and Drug Administration (FDA) approval, dabigatran, is a direct thrombin inhibitor. The other two approved medications, rivaroxaban and apixaban, are selective factor Xa inhibitors. Unlike warfarin and heparin, specific clinical guidelines pertaining to the TSOACs do not address reversal in the case of bleeding. This poses a challenge to the emergency clinician who is likely to encounter patients on these medications who are bleeding. For all three medications, the PT and activated PTT are insensitive in excluding clinically relevant drug concentrations. As discussed in the Diagnostic Testing section, thrombin time may be used for drug quantification of dabigatran, and anti-Xa activity may be used for drug quantification of rivaroxaban and apixaban. Because of the short half-life of these agents, in mild to moderate bleeding, clinical support and observation while holding anticoagulation may be sufficient in most patients. In severe life-threatening bleeding, prothrombin complex concentrate is recommended to support reversal as no specific reversal agents are currently approved. In addition, dialysis may be considered in cases involving dabigatran, because approximately 57% of the drug is removed with 4 hours of dialysis. In the case of apixaban, activated charcoal has been shown to reduce absorption if given within 6 hours of ingestion. Several TSOAC specific reversal agents are currently in development.

Disseminated Intravascular Coagulation

When planning therapy, the emergency clinician needs to remember that DIC is secondary to a serious underlying pathologic process. Once the diagnosis is confirmed, the initial treatment is focused on reversal of the triggering mechanism. Many episodes of DIC are self-limited, such as in a transfusion reaction, or compensated, such as in association with a tumor mass, and do not require intervention other than support.

Replacement therapy is usually instituted simultaneously with attempts to control the primary process. The goal is to avoid depletion of clotting factors. Treatment is partially based on which of the two major pathologic components of DIC dominates the clinical picture. If active bleeding is present, replacement therapy with platelets, fresh frozen plasma, and cryoprecipitate (I, V, VIII) is recommended. Selective replacement therapy can be based on the laboratory and clinical response. Retardation of bleeding, a decrease in fibrin degradation products, and a rise in platelet counts and fibrinogen levels are useful monitors. Normalization of clotting times occurs too late to be of value in monitoring.

Heparin has selective use in the treatment of DIC when fibrin deposition and thrombosis dominate the pathologic picture. Certain disease states are associated more with fibrin deposition, in which case heparin therapy should be considered. Examples include purpura fulminans, retained dead fetus before delivery, giant hemangioma, and acute promyelocytic leukemia. Heparin therapy is of little benefit in cases of meningococcemia, abruptio placentae, severe liver disease, and trauma. Low doses of heparin (300 to 500 units/hr) as a continuous infusion are currently recommended. LMWH may also be used instead of UFH. Continuous monitoring of the clinical response, heparin levels, and bleeding status is necessary.

Other therapeutic agents, such as antithrombin III and activated protein C, have been evaluated. However, none has demonstrated an improved outcome in DIC, and only recombinant activated protein C (drotrecogin alfa) has been associated with improved outcomes in septic shock, regardless of whether DIC was present.

The goals of emergency care of patients with DIC include initial recognition, pursuit of the diagnosis, understanding of potential life-threatening complications, and only rarely initiation of therapy.

**DISPOSITION**

All patients with bleeding disorders of unknown cause or of a significant degree should be admitted to the hospital for further evaluation. The circumstances in which a patient with a known bleeding disorder may be discharged for home care are discussed in earlier sections on individual disease states. Transfer of these patients may be necessary, particularly if hematologic consultation is not readily available. The standard criteria of hemodynamic stability, appropriate monitoring, and full knowledge and understanding on the part of the family and accepting physician should be met before transfer. Because of the delayed bleeding pattern in hemophiliacs, long distance transports may be especially hazardous. Therefore, the importance of advance knowledge and preparation is emphasized. Outpatients are usually treated under the auspices of the hematologic consultant. Early notification and appropriate follow-up arrangements should be made with these specialists.

**KEY CONCEPTS**

- Although hemostatic disorders are confirmed by specific patterns of laboratory test results, a careful history and focused physical examination are often the key to the diagnosis of hematologic diseases.
- All patients with bleeding disorders of unknown cause or of a significant degree should be admitted to the hospital for further evaluation.
- The frequency of hemostatic disorders seen in the ED is unknown; however, they are likely to be more common than thought. Although classic diseases such as hemophilia and DIC are uncommon, the use of antplatelet and anticoagulation agents is common in other disease states, such as cardiovascular diseases.
- Hemophilia patients are often highly informed about their disease. Patient input should be solicited and respected, and early consultation with the patient’s hematologist is encouraged. Consider early treatment with replacement factor while diagnostic testing proceeds.
- Patients with active life-threatening bleeding who are thought to have a congenital bleeding disorder can be supported with fresh frozen plasma, 15 mL/kg, while diagnostic studies are being performed.
- Platelet dysfunction is often equated with low platelet counts. Even though critical thrombocytopenia increases the risk of bleeding, particularly with trauma and surgery, dysfunction can occur at normal counts. For example, aspirin therapy and renal disease can alter platelet function without reducing blood counts.
- All evaluations of suggested ITP should include a complete blood count, peripheral smear, antinuclear antibody test, and bone marrow examination.
- TTP should be suspected in the setting of thrombocytopenia and microangiopathic hemolytic anemia and early treatment with plasma exchange therapy should be initiated even in the absence of the classic pentad. Platelet replacement should be avoided.

CHAPTER 114: QUESTIONS & ANSWERS

114.1. Platelet counts below what level may be associated with severe spontaneous hemorrhage?
   A. 100,000 mm<sup>3</sup>
   B. 50,000 mm<sup>3</sup>
   C. 20,000 mm<sup>3</sup>
   D. 10,000 mm<sup>3</sup>
   E. 5000 mm<sup>3</sup>

   Answer: C. Remember that the count provides no information about the adequacy of platelet function.

114.2. An elevated partial thromboplastin time (PTT) may be caused by an abnormality or deficiency in which of the following?
   A. Calcium
   B. Factor VII
   C. Factor XIII
   D. Fibrinogen
   E. Platelets

   Answer: D. The PTT tests the components of the intrinsic and common pathways—essentially all factors except VII and XIII. Fibrinogen function is reflected in both prothrombin time (PT) and PTT values. Calcium derangements do not typically cause aberrations in PT or PTT.

114.3. Which of the following statements regarding bleeding resulting from a platelet disorder is true?
   A. Males are affected more than females.
   B. Most platelet disorders are inherited.
   C. Preceding trauma does not usually cause the bleeding incident.
   D. Prothrombin time (PT) and partial thromboplastin time (PTT) may both be elevated.
   E. The bleeding often presents as hemorrhage or muscle hematoma.

   Answer: C. Platelet abnormalities are seen most commonly in females and are acquired, often because of drugs, infections, or triggered immunologic mechanisms. The bleeding is typically capillary and does not involve joints or deep muscle. Most of the bleeding is spontaneous.

114.4. A 48-year-old man presents with complaints of leg pain and swelling. Physical examination is remarkable for right lower extremity pallor, mild edema, and absent distal pulses. Laboratory examination is remarkable only for a platelet count of 21,000/mm<sup>3</sup>. Which of the following statements is true?
   A. A history of a recent blood transfusion is likely.
   B. A history of intravenous cocaine use is likely.
   C. A recent viral illness is likely.
   D. Recent digoxin use is likely.
   E. Recent heparin use is likely.

   Answer: E. Heparin-induced thrombocytopenia (HIT) is characterized by post heparin thrombocytopenia (onset 7 to 40 days) and arterial or venous thrombosis. Intravenous cocaine, digoxin use, sulfonamide use, phenytoin use, recent blood transfusion (PLA1 antigen mediated—usually a precipitous drop in platelets 1 week post-transfusion) are all associated with thrombocytopenia but not thrombosis. Treatment of HIT is with direct thrombin (lepirudin) or factor Xa (fondaparinux) inhibitors.

114.5. A 4-year-old boy is brought to the emergency department (ED) by his parents, who report several days of easy bruising on his lower extremities with even minor trauma. He has no past medical history and takes no medications. Physical examination is remarkable for a well-appearing child with lower extremity ecchymoses and some petechiae. You do not suspect child abuse. Laboratory evaluation reveals the following: white blood count (WBC) count, 9300/mm<sup>3</sup>; hemoglobin (Hb), 12.6 g/dL; hematocrit (Hct), 37%; and platelet count (Plt), 21,000/mm<sup>3</sup>. Which of the following statements regarding this scenario is true?
   A. A history of antecedent viral illness is likely.
   B. Coagulation factor levels are probably low.
C. Corticosteroids are indicated.
D. Platelet transfusion is indicated.
E. The adult form of this entity is of shorter duration.

**Answer:** A. Idiopathic thrombocytopenia purpura is an autoimmune process. In children, it typically follows an antecedent viral illness and remits spontaneously in 90% of cases. Steroids are not helpful. Platelet transfusion is rarely, if ever, required. Coagulation factors are not affected. The adult form is more insidious, chronic, and more likely to be associated with systemic disease, such as lupus or lymphoma.
INTRODUCTION

As improved therapy prolongs the lives of cancer patients, the prevalence of oncologic emergencies continues to increase. However, nonspecific clinical features misattributed to the underlying cancer complicate their diagnosis. In this chapter, we review febrile neutropenia, metastatic spinal cord compression (MSCC), malignant pericardial disease, hypercalcemia of malignancy, tumor lysis syndrome (TLS), leukostasis, and superior vena cava (SVC) syndrome.

FEVER NEUTROPENIA

Principles

Whether due to underlying malignancy or as a cytotoxic effect of chemotherapeutics, cancer patients regularly experience depleted levels of circulating neutrophils. Risk of infection rises when a patient’s absolute neutrophil count (ANC) drops below 1000 cells/mm³. However, the increase in risk is most marked in patients with ANC less than 500 cells/mm³. Historically, ANC of 1000 to 1500 cells/mm³ has been considered mild, 500 to 1000 cells/mm³ moderate, and more than 500 cells/mm³ severe. Current guidelines do not emphasize these gradations, and neutropenia is defined as an ANC less than 500 cells/mm³ or an ANC expected to drop below this threshold within 48 hours. Neutropenic patients remain particularly susceptible to infection, even from their own existing microbial flora. The ANC is calculated from a complete blood count (CBC) with differential count by the following formula:

\[
\text{ANC} = \left( \frac{\% \text{ granulocytes} + \% \text{bands}}{100} \right) \times \text{total WBC count}
\]

Infection in a neutropenic patient carries significant mortality risk. For patients experiencing neutropenic fever, overall mortality approaches 20%; and when compared with controls not experiencing neutropenic fever, hazard ratios for overall mortality and mortality during the first chemotherapy course are 1.35 and 1.15 respectively. Most commonly, neutropenic fever is caused by pneumonia, anorectal lesion, skin infection, pharyngitis, or urinary tract infection. However, because local inflammatory responses are dampened by the absence of granulocytes, the only sign of infection may be fever. Defined as a single inflammatory response, fever is caused by pneumonia, anorectal lesion, skin infection, rashes, dysuria, cough, dyspnea, and pain at any location, including the abdomen, chest, joints, throat, sinuses, and ears. Specific note should be made of indwelling venous catheters, because these increase the risk of bacteremia and skin infection. To evaluate for perianal infection, the perineal region should be examined and inquiry made about pain with defecation. Although there is no hard evidence, expert opinion suggests against digital rectal examination to avoid compromise of the barrier between blood and rectal flora. Due to the chemosensitivity of the rapidly dividing epithelial cells of the mouth, mucositis is a common adverse effect of chemotherapy and provides a portal for oral flora into the bloodstream. This can be evaluated by examination and inquiry about oral pain.

Differential Diagnoses

Causes of fever in cancer patients are varied and include infection, venous thrombus or embolus, adverse effect of chemotherapy or other medication, and direct effect of tumor burden. A clear source of infection is identified in only about one-third of neutropenic fever cases. Nonetheless, because of the potentially life-threatening effects of an infection in this population, all febrile neutropenic patients warrant empirical antibiotics and a full evaluation for an infectious source.

Diagnostic Testing

Neutropenic patients with fever should have at least two sets of blood cultures drawn before administration of antibiotics. Both may be drawn peripherally in patients without preexisting central access. In patients with a preexisting central line, one of the two blood cultures should be obtained peripherally, whereas other cultures should be simultaneously drawn off each lumen of the central catheter. Bacterial growth in the catheter-drawn samples greater than 2 hours prior to the peripheral samples is suggestive of a catheter-associated infection. Patients with neutropenic fever should also have a CBC with differential count performed to assess severity of neutropenia, as well as urinalysis, urine culture, chemistries, and renal and hepatic function tests. Additional cultures may be sent according to the clinical presentation (eg, sputum culture if productive cough, stool culture and testing for Clostridium difficile if diarrhea or abdominal pain).

Initial imaging usually consists of chest x-ray, although at least one prospective observational study suggests that this will be low-yield in the absence of specific respiratory symptoms. If fever persists for 72 hours without identified source, empirical computed tomography (CT) scan of the chest and sinuses, and bronchoalveolar lavage may be considered to evaluate for occult fungal infection. Directed CT scans may be performed sooner in the setting of appropriate clinical signs (eg, chest CT for a patient with coughing and bronchial breath sounds, but a clear chest x-ray, abdominal CT for a patient with unexplained abdominal tenderness).
Management

Febrile neutropenic patients should receive antibiotics prior to confirmation of an infectious source. Recommendations for specific regimens are based on risk of clinical decompensation. According to the Infectious Disease Society of America (IDSA), high-risk features include an expected duration of neutropenia greater than 7 days, expected nadir ANC less than 100 cells/mm³, hypotension, pneumonia, new-onset abdominal pain, neurologic changes, or existence of other significant medical comorbidities. The European Conference on Infections in Leukemia (ECIL) also suggests that additional high-risk features include a current or prior infection with a resistant organism and treatment at a center with a high prevalence of resistant organisms. Alternatively, the Multinational Association for Supportive Care in Cancer (MASCC) risk index identifies low-risk patients based on clinical features (Table 115.1). Patients scoring at least 21 points are considered low-risk, because nearly 90% of cases have uncomplicated resolution of their fever within 5 days.

High-risk patients should receive a parenteral, broad-spectrum antibiotic regimen. Local antibiograms should be considered when choosing specific agents, but guidelines recommend monotherapy using a broad-spectrum beta-lactam with antipseudomonal coverage, such as ceftazidime, cefepime, piperacillin-tazobactam, or a carbapenem. Although a meta-analysis suggests an increased rate of all-cause mortality with cefepime use and a decreased rate with piperacillin-tazobactam, most studies comparing broad-spectrum beta-lactams suggest they offer similar rates of effectiveness and survival. A fluoroquinolone or aminoglycoside may be added. However, a meta-analysis of studies comparing beta-lactam monotherapy with combination beta-lactam/aminoglycoside therapy showed that patients receiving aminoglycoside had no survival benefit and were more likely to have adverse effects. A meta-analysis of studies comparing beta-lactam monotherapy with combination beta-lactam/aminoglycoside therapy showed that patients receiving aminoglycoside had no survival benefit and were more likely to suffer adverse events, including nephrotoxicity and fungal superinfection. We recommend antipseudomonal beta-lactam monotherapy for patients with neutropenia and fever. Further empirical antibiotics administered will depend on clinical presentation and consultation with oncology or infectious disease consultants.

Despite increasing rates of bacteremia with gram-positive organisms in cancer patients, randomized-controlled studies and meta-analyses have failed to demonstrate a survival benefit to immediate empirical gram-positive coverage, but rather suggest increased rates of adverse effects. Empirical gram-positive therapy is not recommended except in cases of suspected cellulitis, catheter-associated infection, or pneumonia, or in the case of clinical instability. Similarly, a different randomized-controlled trial failed to show a benefit in immediate, empirical antifungal therapy with voriconazole on the rate of invasive fungal infections. Guidelines suggest against immediate antifungal therapy, unless there is specific concern for a fungal source, in which case, one meta-analysis suggests liposomal amphotericin B to be the most effective agent.

Neutropenic patients with community-acquired pneumonia should be covered for atypical pathogens and possibly pneumocystis pneumonia (PCP). For patients with gastrointestinal symptoms, one randomized controlled trial suggests improved 28-day survival with cefepime/metronidazole combination therapy when compared to piperacillin-tazobactam monotherapy. Patients with a vesicular rash or other evidence of herpes infections should receive empirical acyclovir.

Although some observational studies suggest worsening mortality associated with delays in antibiotic administration, this finding is not universal. No specific timing of antibiotic administration is recommended in the official guidelines at present. Nonetheless, we recommend that high-risk patients receive antibiotic therapy as soon as possible after obtaining blood cultures.

Observational studies and a meta-analysis have demonstrated that low-risk patients may be treated with an enteral regimen, usually amoxicillin/clavulanate and ciprofloxacin, but moxifloxacin monotherapy has shown similar outcomes. Alternatively, low-risk patients may be started empirically on a parenteral broad-spectrum therapy with transition to an enteral regimen after 24 to 48 hours if no complications arise.

Disposition

Regardless of risk category, the majority of febrile neutropenic patients will be hospitalized for observation and initial treatment, ideally to a unit specialized for oncology patients. Hemodynamically unstable patients and those with a deteriorating course should be admitted to an intensive care unit (ICU). A small fraction of patients may be treated with enteral antibiotics in the outpatient setting. These patients should (1) meet low-risk criteria; (2) have no evidence of pneumonia, line infection, cellulitis, or organ failure; (3) have reliable daily follow-up with their oncologist; and (4) demonstrate clinical stability during observation in the emergency department (ED) for at least 4 hours. Reliable follow-up must be ensured, and discharge should only be made following discussion with the patient’s oncologist.

*A score of 21 or greater suggests low-risk of complication and likely resolution of fever within 5 days. COPD, Chronic obstructive pulmonary disease.

| KEY CONCEPTS |

- Patients whose absolute neutrophil count is or is expected to soon be 500 cells/mm³ or less are considered severely neutropenic. A single temperature of 38.3°C or sustained temperature of 38.0°C for at least 1 to 2 hours is considered fever.
- Any neutropenic patient with fever or with infectious signs or symptoms (even in the absence of fever) should be worked up for an infectious source, including drawing of blood cultures, and started on empirical antibiotics. Those with high-risk features (eg, prolonged or profound neutropenia, pneumonia, hypotension, abdominal pain, neurologic changes, MASCC score <21) should be started on an antipseudomonal beta-lactam (eg, cefepime, piperacillin-tazobactam, antipseudomonal carbapenem). Those with low-risk features may be appropriate for oral antibiotics. Empirical gram-positive bacterial, antifungal, and antiviral coverage is unnecessary unless the clinical situation dictates otherwise.
- Neutropenic patients with fever should generally be hospitalized, including all high-risk patients. Select low-risk patients may be managed as outpatients.

**METASTATIC SPINAL CORD COMPRESSION**

**Principles**

Malignancy-related compromise of the spinal cord most commonly occurs from an extradural neoplasm that has hematologically metastasized to the vertebral column. The lesion then typically expands locally from the marrow space through a vertebral vein foramen to invade the spinal canal. Although the resulting cord injury is termed metastatic spinal cord compression (MSCC), direct nerve compression by tumor is uncommon. Cord injury is more commonly caused by occlusion of the epidural venous plexus, leading to breakdown of the blood-cord barrier and vasogenic edema. If untreated, tumor expansion eventually leads to arterial obstruction, causing cord ischemia and infarct. Less commonly, direct compression of the cord over time may lead to demyelination and axonal injury.

The most common tumors causing MSCC are prostate, breast, and lung cancer, each accounting for about 15% to 20% of total cases. Renal cell cancer, non-Hodgkin lymphoma, and multiple myeloma each account for an additional 5% to 10% of all cases. Most cases of MSCC affect the thoracic spine (60%), with the lumbosacral and cervical spine each making up 25% and 15% of cases, respectively. Twenty to forty percent of patients with MSCC have multiple loci of spinal metastasis.

**Clinical Features**

Back pain, weakness, sensory loss, and autonomic function loss are the most frequent presenting symptoms of MSCC. Back pain occurs in more than 95% of patients with MSCC and is the most common initial symptom. Extremity weakness occurs in up to 75% and generally (but not always) precedes sensory loss, which is found in nearly 70% of patients presenting with MSCC. Present in almost 60% of patients with MSCC, autonomic nerve dysfunction, including loss of bowel or bladder function, is a late finding and rarely presents in isolation.

**Differential Diagnoses**

In addition to MSCC, patients with back pain with or without neurological symptoms should be considered for nonmalignant musculoskeletal etiologies (eg, muscle strain/sprain, pathological fracture, disc displacement, radicular stenosis, vertebral osteoarthritis) and paraspinal or vertebral infections (eg, paraspinal abscess, vertebral osteomyelitis, discitis). In patients with known malignancy, new back pain or neurological deficits (motor, sensory, or autonomic) may be up to 100% specific for MSCC, and this diagnosis should be presumed until proven otherwise. In patients without known cancer, however, new back pain is the heralding symptom of cancer in 20% of cases of MSCC, which commonly takes up to 2 months from original presentation to diagnose.

**Diagnostic Testing**

A thorough physical examination should be performed, including palpation of the entire spine, as well as testing of strength, sensation, deep tendon reflexes, and rectal tone. The diagnosis is confirmed by imaging, for which magnetic resonance imaging (MRI) has become the gold standard with sensitivity of 93% and specificity of 97% (Figure 115.1). Even in patients in whom MSCC has been established by another modality, MRI should still be performed when possible, because its added resolution changes treatment strategy in approximately 50% of cases. Because of the 20% to 40% incidence of multiple separate lesions occurring simultaneously, both the thoracic and lumbar spine should be imaged in any patient with MSCC. Although the incidence of a second lesion in the cervical spine is only around 1%, this segment should ideally be included when possible.

If MRI is unavailable or contraindicated (eg, patients with incompatible pacemakers), CT scan of the spine is the next most informative study. If vertebral metastasis is seen on initial scans, presence of cord compression can be assessed by CT myelography, in which contrast is introduced into the subarachnoid space. Sensitivity of this technique rivals that of MRI, but MRI offers similar information noninvasively. Thus, CT myelography is reserved for those rare patients in whom MRI is contraindicated, but radiographic confirmation of cord compression as the cause of symptoms is required prior to intervention.

Plain radiographs and radionuclide scans may demonstrate vertebral metastasis, but sensitivity is limited. Furthermore, these techniques provide no information about the state of the spinal cord itself or the precise location of suspected compression.

**Management**

Treatment of MSCC in the ED entails administration of corticosteroids and initiation of definitive treatment with surgery, radiation therapy, or both. Corticosteroids provide the most immediately available therapy for cord compression; unlike surgery or radiation, their administration does not require significant logistical planning or knowledge of the exact anatomic location of tumor. Early steroid administration has been shown to improve ambulation rates at 3- and 6-month intervals, and patients receiving corticosteroids have improved long-term pain scores. Current guidelines suggest a 10 mg intravenous bolus of dexamethasone...
followed by 16 mg orally per day in divided doses for any patient with neurological deficits believed secondary to MSCC. Patients with severe deficiencies, such as paraplegia, may receive a higher dose of 100 mg intravenous dexamethasone, followed by 96 mg orally per day in divided doses. However, steroids may be unnecessary in patients with vertebral metastases on imaging without neurological deficits.

Corticosteroids temporize vasogenic cord edema, but cord damage will ensue without definitive correction with radiation therapy, surgery, or both. For patients who can tolerate surgery and have goals of care in line with surgery, a combination of surgical decompression followed by radiation therapy provides superior long-term rates of continence, ambulation, and survival than radiation therapy alone, and combined management is recommended in the most recent guidelines. Surgical intervention is especially important in patients with spinal instability, cord compression by bony fragments, sphincter dysfunction, tumor histology known to be radio-insensitive, or compression in an area that has already received a maximum allowable radiation dose.

Thirty-day mortality rates for spinal cord decompression exceed 10% and overall complication rates exceed 50%. For patients unable to tolerate surgery or with incompatible goals of care, radiation alone may be pursued. If surgery is anticipated, it should precede any radiation treatment to prevent wound healing complications. Although external beam radiation remains the standard of care, newer techniques such as radiosurgery and stereotactic body radiation therapy provide more focused radiation treatment with less collateral damage to surrounding tissues.

Although no direct evidence exists to guide the exact timing of treatment, most experts recommend definitive treatment within 24 hours whenever possible. Neurological status at initiation of treatment is the strongest indicator of outcome, and every effort should be made to expedite appropriate therapy to prevent further neurological decline.

Disposition

Following corticosteroid administration, patients with neurological deficits (ie, motor, sensory, or autonomic) should be hospitalized for definitive therapy. Asymptomatic patients with incidentally noted vertebral metastasis may be managed as outpatients, provided they have reliable follow-up.

**KEY CONCEPTS**

- Vertebral metastasis and spinal cord compression should be considered in any patient, particularly those with known cancer who have back pain, peripheral strength or sensory loss, or loss of bowel or bladder function.
- MRI of the spine is the preferred diagnostic test when evaluating spinal cord compression. CT of the spine with myelography may be performed if MRI is contraindicated or unavailable. Plain films are not sufficiently sensitive to rule out spinal cord compression.
- Intravenous corticosteroids (dexamethasone 10 mg bolus) should be given to any patient with neurological deficits from known or suspected MSCC. Consideration should be given to emergent surgical and radiotherapeutic intervention if compatible with goals of care.

**MALIGNANT PERICARDIAL DISEASE**

Principles

Pericardial manifestations of malignant disease, including pericarditis, pericardial neoplasm (usually metastatic), and pericardial effusion affect greater than 10% of cancer patients and cause about 25% of all effusive pericardial disease in the developed world. Approximately two-thirds of malignancy-associated pericardial disease is clinically insignificant. However, in the remaining one-third of cases, hemodynamic compromise, organ failure, or death occur.

Neoplastic disease is believed to cause pericardial effusion when lymphatic flow, which normally drains fluid from the pericardium, becomes obstructed or reversed by congestion in proximal malignant lymph nodes. An effusion develops both by obstruction of fluid outflow, and by metastatic spread to the pericardial lining, leading to a non-physiologic increase in pericardial fluid production. The most common culprits in this process are lung, breast, and hematologic tumors, as well as melanoma. Effusions not directly caused by malignancy may also develop in cancer patients secondary to hypoalbuminemia or as an adverse effect of radiation or chemotherapy.

Although the pericardial sac has the elastic potential for gradual expansion to more than 1 L, it is poorly distensible in short (ie, hours to days) timeframes, and rapid accumulation of even a few hundred milliliters of fluid may precipitate cardiac tamponade. This life-threatening condition occurs when intra-pericardial pressures rise to match or surpass those of the atra and then ventricles, reducing or eliminating cardiac output and leading to shock.

Clinical Features

The classic presenting symptoms of pericardial disease are dyspnea and chest pain. Weakness and fatigue are often associated, and large, slowly accumulating effusions may result in mass-effect on nearby structures, causing nausea, early satiety, cough, hiccups, hoarseness, or dysphagia. Cardiac tamponade presents with shock, but other classic stigmata of the disease are unreliable. Pulsus paradoxus, defined as a 10 mm Hg systolic blood pressure gradient between inspiration and expiration in the respiratory cycle, is the most sensitive sign, present in about 80% of cases. Kussmaul’s sign (paradoxically increased jugular venous pressure [JVP] with inspiration) and Beck’s triad (hypotension, elevated JVP, and muffled heart sounds) are seen in less than half of cases. Hypotension may not even be a presenting symptom, particularly in patients with underlying hypertension.

Differential Diagnosis

Because of its nonspecific presentation, the differential diagnosis for malignant pericardial effusion is broad. Considerations should include acute coronary syndrome, acute heart failure or valve failure, pulmonary embolism, pleural effusion, pneumonia, and pneumothorax.

Diagnostic Testing

Evaluation for a patient with suspected malignant pericardial effusion should include chest radiography, electrocardiogram (ECG), and transthoracic echo (TTE). Electrocardiographic manifestations may include nonspecific ST or T changes, or low amplitude QRS voltage. Electrical alternans (alternating high and low QRS amplitudes) is only seen in 10% of cases. An enlarged cardiac silhouette on chest x-ray may suggest a large effusion. Echocardiography, which approaches 100% sensitivity and specificity for pericardial effusion, can also identify the cardiac chamber collapse characteristic of tamponade physiology. Emergency clinicians, who are trained in basic bedside cardiac ultrasound, can reliably identify pericardial effusion and should perform the initial examination to hasten diagnosis (Figure 115.2).
Management

Malignant pericardial effusion generally serves as evidence of advanced cancer, and therapies should be tailored to match each patient’s goals of care. If aggressive therapy is desired, cardiac tamponade is a medical emergency and warrants immediate drainage, ideally under real-time ultrasonographic guidance (Figure 115.3). Ultrasound-guided drainage by the intercostal approach results in fewer complications and higher success rates than blind drainage by subxyphoid approach. If ultrasound is unavailable, a subxyphoid approach should be employed by inserting the needle at a 15° angle to horizontal between the xiphoid process and left costal margin. After clearing the rib cage, the needle should be leveled and advanced toward the left shoulder until return of fluid is achieved. Temporizing measures such as inotropes (epinephrine in hypotensive patients, dobutamine in normotensive patients) or intravenous fluids may be attempted, but, despite early successes in trials on anesthetized animal models, these measures have not demonstrated reproducible benefit in humans and should not be viewed as a substitute for timely drainage.

Effusion without tamponade can be managed non-emergently. Fluid sampling for cytology and tumor marker analysis can help confirm etiology of effusion. This also allows intrapericardial...
HYPERCALCEMIA

Principles
Serum calcium regulation is achieved by parathyroid hormone (PTH) and calcitriol (the activated form of vitamin D), which both increase serum calcium level, and to a lesser extent by calcitonin, which decreases it (Figure 115.4). Approximately 30% of cancer patients will experience dysregulation of calcium homeostasis, usually caused by one or more of the following: (1) synthesis of the PTH analog PTH-related protein (PTHrP), (2) overproduction of calcitriol, (3) bone osteolysis due to direct spread of tumor, or, (4) less commonly, ectopic production of PTH. In most cases, malignancy-associated hypercalcemia signifies advanced disease, with median survival of less than 2 months. Synthesis of PTHrP, classically called humoral hypercalcemia, causes about 80% of cases of malignancy-associated hypercalcemia, and is usually associated with squamous cancers, such as lung, esophagus, head and neck, cervical, ovarian, and endometrial carcinomas. Calcitriol overproduction is usually seen in Hodgkin and non-Hodgkin lymphomas, in which secreted cytokines inappropriately activate the vitamin D-activating enzyme 1α-hydroxylase in macrophages. Bony metastasis can cause local cytokine-induced osteolysis and, if extensive, can lead to hypercalcemia. Ectopic PTH production is a rare feature of malignancies, mainly limited to case reports. Primary hyperparathyroidism occurring coincidentally with cancer is much more common.

Disposition
Disposition depends on the hemodynamic effect of the pericardial effusion. Patients without tamponade or with a low likelihood of tamponade in the near future (ie, slow evolution of symptoms) can be managed non-emergently as an outpatient. Those with tamponade or rapid development of effusion should undergo pericardiocentesis and be hospitalized to monitor for re-accumulation of fluid.

KEY CONCEPTS
- Cardiac tamponade occurs when pericardial pressures inhibit cardiac filling and output. No clinical sign or symptom is entirely sensitive for cardiac tamponade, but echocardiogram findings of large pericardial effusion (anechoic stripe around the heart), and atrial or right ventricular collapse during diastole, combined with clinical findings of shock are highly suggestive.
- If compatible with goals of care, pericardial effusion causing tamponade should be emergently drained. Intravenous fluid or inotrope administration may be trialed as a temporizing measure, but these therapies are unreliable and should not delay definitive management.

Differential Diagnoses
Because of its nonspecific presentation, the differential diagnosis for malignancy-associated hypercalcemia is quite broad. Consideration should be given to infection with systemic manifestations, direct neurological injury (such as, cerebrovascular accident or central nervous system [CNS] infection), or other metabolic derangements (such as, hyper- or hyponatremia, acidemia, or TLS).

Fig. 115.4. Schematic representation of normal calcium homeostasis. Signaling molecules are represented by circles, targets of each signaling molecule and effects on the target are represented by green arrows and boxes. Activation of vitamin D by 1α-hydroxylase is represented by a black arrow.
Diagnostic Testing

Accurate measurement of the free serum calcium level is the most important step in the evaluation of malignancy-associated hypercalcemia. Measurements of total serum calcium, which are often included in basic metabolic panels, include a large fraction of physiologically inert calcium, which is bound to albumin and other serum proteins. Approximations of the bound fraction of serum calcium can be made using serum albumin measurements, but factors affecting the avidity of calcium for serum proteins, such as pH and the presence of medications that compete for binding sites, as well as abnormal concentrations of non-albumin proteins, may lead to inaccuracies in this calculation. It is therefore recommended that free or ionized levels of calcium be obtained for any patient with suspected malignancy-associated hypercalcemia.

Testing for additional metabolic abnormalities including serum levels of sodium, potassium, bicarbonate, chloride, magnesium, and phosphorous should be performed, as should assessment of kidney function with blood urea nitrogen and creatinine. A brief review of reversible factors exacerbating hypercalcemia such as thiazide diuretic use or exogenous calcium supplementation may be helpful. Further testing to determine the etiology of malignancy-associated hypercalcemia (PTH, PTHrP, and calcitriol levels, as well as skeletal survey for bone metastasis) may eventually be undertaken but is generally unnecessary in the ED, because initial therapy is not etiology-specific.

Management

Severe hypercalcemia, especially if rapidly developing, will lead to death if untreated. First-line treatment for malignancy-associated hypercalcemia is intravenous fluid. Hypercalcemia impairs renal resorption of water and sodium, leading to hypovolemia. Hypovolemia further limits the kidneys’ ability to eliminate calcium, creating a feedback loop that propagates hypercalcemia and hypovolemia. To break this loop, euvolemia must be restored, generally by administration of intravenous fluid at rates of at least 200 to 500 mL/hr. We recommend that patients with acute oliguria or anuria be vigorously volume challenged, because poor urine output may simply be a product of hypovolemia. However if urine output does not improve, as may be the case with heart or kidney failure, resulting hypervolemia should be treated with a combination of diuresis, dialysis, and positive-pressure ventilation. Historically, loop diuretics have been used even for euvoemic patients in an attempt to force calciuresis; however, this has led to high complication rates and the calciiuretic effect is minimal. We therefore recommend use of loop diuretics only for volume management. Thiazide diuretics enhance distal tubule calcium resorption and should be avoided in hypercalcemic patients. Hypercalcemic patients with baseline oliguria or anuria may require dialysis.

Bisphosphonates are the primary pharmacologic treatment for hypercalcemia. Analogs of pyrophosphate, which is produced in bone catabolism, bisphosphonates inhibit bone turnover by reducing osteoclast function and directly stabilizing hydroxyapatite crystals. Typical regimens consist of single doses of either 90 mg of pamidronate given over 2 to 4 hours, or 4 mg of zoledronate given over 5 minutes. Both should be given intravenously, because oral availability may be limited. An average reduction of serum calcium concentration of 3 to 4 mg/dL can be expected with either regimen, but maximum effect may not be seen for 7 to 10 days. Bisphosphonates can cause an acute phase reaction in up to one-third of cases, consisting of fever, myalgia, arthralgia, and headache, usually within 36 hours. Such side effects can be managed with antipyretics and antihistamines. Bisphosphonates have also been associated with renal dysfunction and jaw osteonecrosis.

Although effective, bisphosphonates require days to lower serum calcium levels. Calcitonin has a quicker onset (12 to 24 hours) and may be useful for manifestations of hypercalcemia requiring immediate reduction of serum calcium level, such as dysrhythmias. The effects of calcitonin are short-lived due to tachyphylaxis, so definitive therapy with bisphosphonates should be simultaneously given. Calcitonin should be given subcutaneously or intramuscularly 4 to 8 units/kg every 6 hours, which typically reduces the serum calcium level by 1 to 3 mg/dL.

Other pharmacological therapies include denosumab, a human monoclonal antibody inhibiting the RANK ligand that has been used in patients with bisphosphate-resistant hypercalcemia, as well as plicamycin (mithramycin) and gallium nitrate, which have both fallen out of favor due to long administration times and unfavorable adverse effect profiles. Hemodialysis can quickly reduce serum calcium levels and should be considered in patients who are dialysis-dependent, recalcitrant to other therapies, or have life-threatening manifestations of hypercalcemia. Regardless of other therapies, treatment of the underlying malignancy should be immediately pursued if this is compatible with goals of care, because this is the only way to reverse the underlying cause of hypercalcemia and generally does not increase serum calcium levels.

Disposition

Patients with severe hypercalcemia (>14.0 mg/dL) or an acutely increasing calcium level should be admitted to a monitored bed. Patients with a stable serum calcium concentration less than 14 mg/dL, and close, reliable follow-up may be managed on an outpatient basis in consultation with the patient’s oncologist and/or primary care doctor.

KEY CONCEPTS

- Calcium levels in hypercalcemic patients should be assessed by measuring ionized calcium concentration, rather than total calcium concentration.
- First-line management of hypercalcemia includes intravenous fluids, and loop diuretics only for volume management, as well as bisphosphate therapy (pamidronate 90 mg or zoledronate 4 mg, intravenously). Calcitonin is faster acting than bisphosphonates, but tachyphylaxis may develop; consider calcitonin in hypercalcemic patients with active cardiac or neurologic symptoms (eg, dysrhythmias, seizures).

TUMOR LYsis SYNDROME

Principles

TLS occurs when destruction of malignant cells occurs with such volume and speed that the body’s mechanisms for regulating the unwanted products of this destruction are overwhelmed. Such cell lysis releases intracellular contents, causing hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Acute kidney injury, caused by crystal deposits of uric acid or calcium-phosphate in the renal tubules or by crystal-independent mechanisms of damage by uric acid, often accompanies TLS, further compounding the patient’s ability to regulate serum electrolyte levels and eliminate products of cellular destruction. TLS is most likely to occur in patients with tumors that are high-burden, rapidly growing, and highly chemosensitive, such as Burkitt’s lymphoma or acute lymphoblastic leukemia (ALL). TLS occurs less commonly in rapidly growing solid tumors, such as breast, testicular, and small cell lung cancers; overall the diversity of malignancies with potential for TLS is growing as we develop more effective and fast-acting chemotherapeutics. Patient
factors predisposing to TLS include preexisting renal failure, hypovolemia, and hyperuricemia.

Clinical Features

Although spontaneous TLS is possible, patients undergoing cytotoxic therapy are particularly at risk for TLS. Symptoms result from metabolic derangements or kidney failure and include nausea, vomiting, lethargy, confusion, edema, seizure, myalgia, and tetany; dysrhythmias may result in cardiac arrest. Release of immunoactive proteins such as cytokines from lysed cells may cause sepsis-like symptoms.31 Due to the immunocompromised state of these individuals, an infectious source should be presumed in patients with septic symptoms and empirical antibiotics should be administered. Electrocardiographic changes may include QT interval prolongation due to hypocalcemia and P-wave flattening, PR and QRS interval prolongation, and T-wave peaking due to hyperkalemia.

Differential Diagnoses

Differential diagnosis for patients with TLS varies with presenting symptoms. For those with nonspecific symptoms such as fatigue or myalgia, consideration should be given to other metabolic derangements such as malignancy-associated hypercalcemia, or systemic manifestations of an infectious source. Patients presenting with cardiac dysrhythmia should be considered for acute coronary syndrome, pulmonary embolism, other sources of metabolic derangements, and other causes of myocardial irritation. Seizure and other neurologic symptoms may suggest cerebrovascular accident, CNS infection or metastasis, or other metabolic abnormalities.

Diagnostic Testing

Evaluation begins with measurement of serum potassium, phosphate, ionized calcium, urea nitrogen, creatinine, uric acid, and lactate dehydrogenase (LDH). If the patient is presenting with sepsis-like symptoms, investigation for a source including cultures and appropriate imaging should be undertaken. Renal imaging (eg, ultrasound) to rule out obstructive pathology as well as urinalysis and measurement of fractional excretion of sodium (FE\textsubscript{Na}) should be performed for patients presenting with acute kidney injury. Further evaluation may be indicated by specific presenting symptoms, such as head imaging for patients presenting with seizure, or abdominal imaging for patients with nausea and vomiting.

Management

Intravenous fluids to promote renal clearance of unwanted metabolites should be the initial therapy for TLS; volumes of 3 L/m\textsuperscript{2}/day are suggested, or as high as 5–6 L daily. Acutely oliguric or anuric patients should be similarly fluid challenged because these may be the result of hypovolemia, but plans should be made for diuresis or renal replacement therapy if urine output does not improve or hypervolemia ensues. Patients with oliguria or anuria at baseline may require initial management with renal replacement therapy. Although previously recommended, treatment guidelines no longer support alkalization of the urine, because this may instigate worse metabolic derangements, including phosphate nephropathy and xanthine crystal nephropathy.31

Hydration provides the primary therapy for hyperphosphatemia, but limiting dietary phosphate intake and eliminating phosphate-containing supplements are indicated. Hypocalcemia is a direct result of free calcium precipitating with excess phosphate to form the insoluble, nephrotoxic compound calcium phosphate. The extent of calcium phosphate formation is directly related to the product of serum calcium and phosphate concentrations. Products greater than 55 suggest a worsened long-term risk of calcium phosphate deposition in the viscera, although short-term outcomes are not well studied. To minimize the risk of calcium phosphate nephropathy, asymptomatic patients should go without calcium repletion. Patients with cardiac (eg, dysrhythmia, heart blocks) or neurological (eg, seizure, coma) manifestations of hypocalcemia should receive intravenous calcium repletion.

Management of hyperkalemia is the same as that from any other etiology. Intravenous calcium given as a bolus can transiently (less than 1 hour) stabilize the myocardium of patients with existing or an imminent dysrhythmia (eg, QRS widening). Efforts can then be made to shift potassium intracellularly via administration of insulin, bicarbonate, and beta-agonists. Ultimately potassium must be removed from the body by the gastrointestinal tract with administration of potassium binders, by the kidneys with hydration and possibly loop diuretics, or by dialysis.

Uric acid is a metabolite in the degradation pathway of nucleic acids. Hyperuricemia from massive release of free nucleic acids can cause nephropathy both directly and by crystal formation in the renal tubules.34 In addition to hydration, hyperuricemia can be managed pharmacologically by administration of allopurinol or rasburicase. Allopurinol, an analog of the uric acid precursor xanthine, competitively inhibits enzymatic conversion of xanthine to uric acid. Although this decreases uric acid production, it does not eliminate uric acid already present in the body, and it leads to buildup of xanthine, which itself has limited solubility and potential to cause nephropathy. Rasburicase, a recombinant form of the enzyme urate oxidase, eliminates uric acid directly by converting it into the more soluble metabolite allantoin. It is usually given as a single, intravenous dose. Significant reduction in uric acid levels within 1 day have been observed with weight-based doses of 0.05 mg/kg, and with fixed doses of 3 to 6 mg.32,53 Those with glucose-6-phosphate dehydrogenase (G6PD) deficiency should not receive rasburicase, because hydrogen peroxide is a byproduct of its activity and this may trigger hemolytic crisis. Methemoglobinemia may also result from rasburicase administration.35

Disposition

The Cairo-Bishop definition of TLS, a systematic classification of lab abnormalities and clinical manifestations of TLS, divides patients with only laboratory manifestations of TLS (laboratory TLS, or LTLS) from those with clinical manifestations of TLS (clinical TLS, or CTLS), such as kidney injury, dysrhythmia, or seizure. Patients with clinical TLS consisting of dysrhythmia or seizure should be admitted to an ICU; those with kidney injury may be admitted to a standard telemetry bed, but ICU care should be considered as mortality in patients with kidney injury and TLS has been observed as high as 50%.55 Patients with laboratory TLS only may be admitted to a monitored bed for observation and treatment.

KEY CONCEPTS

- TLS is manifested by the combination of hyperkalemia, hyperuricemia, hyperphosphatemia, and hypocalcemia, often accompanied by acute renal failure.
- Patients with TLS should have their potassium, phosphate, calcium, and uric acid levels, as well as renal indices monitored closely. Intravenous fluids should be administered, as well as therapies to reverse hyperkalemia. Hyperuricemia may be prevented with allopurinol or treated with rasburicase. Calcium should only be repleted in patients with cardiac or neurologic manifestations of hypocalcemia.
LEUKOSTASIS

Principles
Leukostasis arises when the white blood cell (WBC) count is sufficiently high to cause vascular congestion, leading to organ dysfunction, typically in the lungs or CNS.54 No single threshold exists for leukostasis to occur, and different types of leukemia cells cause leukostasis at widely variable cell counts. Patients with chronic lymphocytic leukemia (CLL) may tolerate WBC counts greater than 500,000 cells/µL, whereas patients with acute myeloid leukemia (AML) may develop leukostasis with WBC count less than 100,000 cells/µL.55

Two mechanisms are believed to drive leukostasis. First, blast cells are larger and less deformable relative to normal WBCs. As the number of blast cells in the blood increases, blood viscosity increases.56 Second, because certain cell types are more prone to causing leukostasis than others with similar size and physical characteristics, intrinsic features of leukemic cells, such as cytokine-induced activation of endothelial adhesion mechanisms, may also contribute.56

Clinical Features
Pulmonary leukostasis presents as dyspnea, tachypnea, and hypoxemia.56 Auscultation of pulmonary leukostasis may mimic lung infection with crackles or rhonchi, and bilateral opacities are often seen on imaging.56 CNS leukostasis may present with confusion, audio or visual abnormalities, headache, ataxia, or coma, and intracranial hemorrhage may be seen on head imaging.56 Other manifestations may include retinal hemorrhage, myocardial infarction, acute limb ischemia, priapism, renal vein thrombosis, and renal infarction.

Differential Diagnoses
Diagnosis of leukostasis is challenging, because symptoms of leukostasis are similar to those of other problems common to leukemia patients. Pulmonary leukostasis presents with similar history, physical examination findings, and imaging as pneumonia or pulmonary edema.

Patients with CNS leukostasis may present with nonspecific alteration of mental status, similar to that seen in metabolic derangement, medication side-effect, or systemic manifestation of infection. Intracranial hemorrhage seen on head imaging may be related to leukostasis itself, or may result from thrombocytopenia or disseminated intravascular coagulopathy (DIC), both of which often accompany hyperleukocytosis.

Diagnostic Testing
The gold standard diagnostic test for leukostasis is the presence of leukocyte-clogged blood vessels on tissue pathology.56 Because this is rarely available, the diagnosis must often be inferred and empirically treated based on knowledge of leukocyte count, cancer type, and clinical picture. A CBC with peripheral smear should be sent from the ED. Further evaluation is indicated to determine cancer type (if not known), including cytology and immunostaining, although this is rarely feasible from the ED. Symptom-specific imaging should be performed, such as chest plain films or CT for respiratory problems, and head CT or MRI for neurologic symptoms. Normal imaging findings does not exclude leukostasis, however. If sent, blood gases should be processed immediately, because metabolically-active leukocytes will continue to consume oxygen in the phlebotomized sample, resulting in falsely low oxygen levels.56

Management
ED management of leukostasis centers on reduction of blood viscosity. Intravenous fluids should be administered to dilute the blood as much as possible. Although patients with hyperleukocytosis are often anemic, transfusion of red blood cells should be avoided in asymptomatic patients, because erythrocytes exacerbate blood viscosity. Platelets and plasma may be given as needed because these components make little or no contribution to blood viscosity.57

The definitive treatment for hyperleukocytosis is reduction of leukocyte count, either by physically removing excess cells using leukapheresis, or by destroying excess cells pharmacologically. Leukapheresis involves continuous removal of fractions of the patient’s blood, selective extraction of leukocytes from the fractions, and return of the remaining product to the patient. Leukapheresis can reduce leukocyte count by 20% to 50% in only a few hours, but insertion of a central large bore catheter is necessary, and leukapheresis requires specialized equipment not available at all institutions.56 Studies of outcomes with and without leukapheresis are small and nonrandomized. Although some symptomatic or short-term survival benefits may exist, no benefits to long-term survival have been demonstrated.56-59 Hydroxyurea, an inhibitor of deoxyribonucleotide synthesis, can pharmacologically reduce leukocyte burden by similar margins over 24 to 48 hours. Chemotherapy induction, which should only be initiated in consult with an oncologist, can also quickly reduce leukocyte count, but the patient should be monitored for signs of TLS. Due to the difficulty of clinically distinguishing leukostasis from other serious pathologies, treatments for other diagnoses may be simultaneously initiated. Such concomitant therapy (eg, antibiotics) is particularly important for suspected pneumonia, because patients with hyperleukocytosis may be functionally neutropenic.

Disposition
Patients with leukostasis require hospitalization for monitoring, hydration, and leukocyte-reducing therapy. Asymptomatic patients with leukostosis also warrant hospitalization if their blast count is greater than 20,000 cells/µL, have a tumor type of AML, or have a new leukemia of unknown type. Patients with asymptomatic hyperleukocytosis who do not meet these criteria may be discharged with close, reliable follow-up, but this decision should be made in conjuction with the patient’s oncologist.

KEY CONCEPTS
- Leukostasis arises due to congestion of blood vessels by excessive numbers of leukocytes. This most often occurs in the lungs and CNS, and the resulting clinical picture may be difficult to differentiate from other diseases which afflict cancer patients (eg, pneumonia, pulmonary embolism, CNS hemorrhage).
- Intravenous fluids should be administered in the ED to reduce blood viscosity, and red blood cell transfusions should generally be avoided. Therapies to lower the WBC count should be performed in consultation with an oncologist, and may include leukapheresis, administration of hydroxyurea, or initiation of chemotherapy.

SUPERIOR VENA CAVA SYNDROME

Principles
The superior vena cava (SVC) spans the final stretch of venous return from the upper body, spanning from the juncture of the
brachiocephalic veins to the heart. The SVC is thin-walled, and blood pressures in the SVC are relatively low (≈2 to 8 mm Hg), making it particularly susceptible to external compression. When SVC flow is compromised, its internal pressure can reach 20 to 40 mm Hg, potentially resulting in symptoms or cardiac decompensation. Such clinical deterioration constitutes SVC syndrome.

Causing greater than 60% of cases, malignancy remains the most common cause of SVC syndrome. Lung cancer and lymphoma cause over 90% of cases of malignancy-induced SVC syndrome. SVC syndrome due to an intraluminal mass, such as thrombosis, is increasing in prevalence. Cancer patients are at high risk for thrombosis due to their hypercoagulable state and indwelling venous catheters in the SVC.61-63

Clinical Features

Patients with SVC syndrome most commonly present with upper extremity, chest, or face edema or erythema, but dyspnea, dysphagia, chest pain, or cough may also be present. Physical examination findings often reflect elevated venous return pressures, including jugular venous distention (JVD) and edema, flushing, or cyanosis of the face, arms, and upper trunk. Distention of the SVC and compression of other nearby structures may cause vocal cord paralysis, blurred vision, and Horner’s syndrome. Pleural effusion may be apparent on chest films or bedside sonography. Overall, the type and severity of symptoms greatly depend on the acuity of SVC compression; patients with a slowly developing obstruction may develop collaterals, which enable asymptomatic high-grade compression.

Differential Diagnoses

Edema and flushing isolated to the upper body is highly suspicious for SVC syndrome, particularly in a patient with known lung cancer or lymphoma. Other considerations include cellulitis or deep tissue infection (eg, Ludwig’s angina), thoracic inlet syndrome, or obstruction of other deep veins (eg, occlusive deep venous thrombosis in an internal jugular vein or subclavian vein). Other symptoms such as JVD, dyspnea, or cough are less specific and may suggest congestive heart failure, pneumonia, pericardial tamponade, or pulmonary embolism.

Diagnostic Testing

Thoracic imaging, and contrast-enhanced CT in particular, is the most important and commonly employed diagnostic modality for SVC syndrome (Figure 115.5), but MRI is a viable alternative. In confirmed cases of SVC syndrome, a tissue diagnosis of the offending mass should be made prior to initiation of treatment.64 This may be obtainable by sputum cytology, or by invasive means, such as bronchoscopy, lymph node biopsy, mediastinoscopy, or thoracotomy. Moderate sedation or general anesthesia may be used safely to enable these procedures, however, in cases involving tracheal compromise, an airway should be emergently and carefully (eg, consideration of awake fiberoptic intubation) established prior to anesthesia induction.65

Management

In the ED, management of SVC syndrome is largely conservative. Elevating the head of bed to promote gravitational drainage of the upper body, and administration of supplemental oxygen, when appropriate, may provide significant symptomatic relief. For patients with SVC syndrome due to obstructing thrombus, anti-coagulation with or without thrombolitics should be initiated.63 Diuretics or steroids have historically been administered, but they have no proven benefit and may simply provoke complications. Although the symptoms of SVC syndrome are unpleasant, risk to life occurs only with the rare and extreme complications of cerebral edema or hemodynamic compromise. Definitive treatment of malignant SVC syndrome can often be safely delayed until biopsy specimens are obtained because of the rare need for emergent therapy and the increasing ability to tailor anti-cancer therapy based on exact tissue diagnosis. Once a histological diagnosis is made, chemotherapy, radiation, and surgery, if indicated, may be tailored to the diagnosis.

Endovascular stenting of SVC may be employed in cases of treatment failure, expected treatment failure (eg, tumor poorly sensitive to radiation or chemotherapy), or hemodynamic compromise or cerebral edema in which immediate patency of the SVC is needed.66 Open surgical bypass or replacement of the SVC can be performed but is reserved for the most extreme cases, because less invasive measures are often successful.67

Disposition

Although SVC syndrome is seldom life threatening, symptomatic relief first requires diagnosis and treatment tailored to the underlying etiology, and hospitalization often expedites this evaluation. Patients with hemodynamic compromise, cerebral edema, or tracheal compromise should be admitted to an ICU following initial stabilization (eg, intubation for tracheal compromise).
CONCLUSION

Oncologic emergencies pose unique challenges because their presentations are often nonspecific and may be mistaken for natural progression of underlying malignancy. Vigilance and clinical suspicion must be maintained whenever treating cancer patients in the ED.

CHAPTER 115: QUESTIONS & ANSWERS

115.1. Which of the following statements regarding infections in cancer patients with febrile neutropenia is true?
A. Blood cultures should be obtained from an indwelling catheter if present.
B. Head computed tomography (CT) is always indicated.
C. Lumbar puncture (LP) should be routinely undertaken.
D. Most isolated pathogens are gram negative.
E. Sinus imagery should be routinely undertaken.

Answer: A. In patients with a preexisting central line, one of the blood cultures should be obtained peripherally while other cultures should be simultaneously drawn off each lumen of the central catheter. Bacterial growth in the catheter-drawn samples more than 2 hours prior to the peripheral samples is suggestive of a catheter-associated infection. Head CT is not routinely indicated. It may be performed if the patient demonstrates focal neurologic deficits, alteration in mental status, or a lumbar puncture is planned. LP and CT scan of the sinuses are not routinely done unless signs or symptoms suggest these are involved.

115.2. A 33-year-old woman with breast cancer presents with fever and neutropenia. She is status post mastectomy and undergoing chemotherapy. Vital signs are remarkable for temperature, 38.8°C; heart rate, 110 beats/min; and blood pressure, 89/50 mm Hg. Examination is otherwise normal. She has no indwelling catheters. Which of the following is the most appropriate empirical antibiotic regimen?
A. Antibiotics should be withheld pending radiographs and cultures
B. Cefepime as monotherapy
C. Ceftazidime and gentamicin
D. Meropenem and vancomycin
E. Ticarcillin and amikacin

Answer: B. Monotherapy with imipenem, meropenem, ceftazidime, or cefepime is as effective as traditional dual therapy with an antipseudomonal penicillin and aminoglycoside. However, vancomycin should be included as well if any of the following exist:
- Hypotension or evidence of cardiovascular impairment
- Clinically suspected catheter infection
- Positive blood cultures for gram-positive organisms
- Known colonization with methicillin-resistant Staphylococcus aureus or cephalosporin-resistant Pseudomonas

115.3. A 57-year-old man presents with exertional dyspnea, facial swelling, cough, and bilateral hand swelling. His past medical history is unremarkable except for many years of heavy smoking. Physical examination is remarkable for moderate conjunctival suffusion, jugular venous distention (JVD), upper extremity venous prominence, and facial plethora. Which of the following statements regarding this patient’s likely condition is true?
A. Corticosteroids are indicted urgently.
B. Intravenous furosemide should be initiated emergently.
C. Treatment depends upon the tissue diagnosis.
D. Urgent radiotherapy is indicated.
E. Venography is the initial test of choice.

Answer: C. Superior vena cava (SVC) syndrome is most commonly caused by lung cancer, although non-oncologic etiologies (thrombosis from indwelling catheter) are increasing. Unless the patient is in acute respiratory distress, emergent interventions are not indicated and intervention should follow tissue diagnosis. The main “rule outs” are congestive heart failure and pericardial tamponade. Diuretics may provide symptomatic relief but are not emergently indicated. Corticosteroids are not useful unless there is airway compromise.

115.4. Which of the following is not a risk factor for acute tumor lysis syndrome (TLS)?
A. High-burden, rapidly growing and highly chemosensitive leukemias.
B. Hypovolemia
C. Old age
D. Preexisting renal dysfunction
E. Rapidly growing solid tumors

Answer: C. TLS is most likely to occur in patients with tumors that are high-burden, rapidly growing, and highly chemosensitive, such as Burkitt’s lymphoma or acute lymphoblastic leukemia (ALL). TLS occurs less commonly in rapidly growing solid tumors, such as breast, testicular, and small cell lung cancers; overall the diversity of malignancies with potential for TLS is growing as we develop more effective and fast-acting chemotherapeutics. Patient factors predisposing to TLS include preexisting renal failure, hypovolemia, and hyperuricemia. Old age is not a known risk factor for TLS.

115.5. A 65-year-old male with a history of a large head and neck tumor presents with symptoms of fatigue, weakness, confusion, depression and malaise, nausea, vomiting, constipation, polyuria, and palpitations. His electrocardiogram (ECG) demonstrates a shortened QT interval. Which of the following electrolyte abnormalities is likely to underlie his presentation?
A. Hypercalcemia
B. Hyperkalemia
C. Hyperuricemia
D. Hypocalcemia
E. Hypokalemia

Answer: A. Approximately 30% of cancer patients will experience dysregulation of calcium homeostasis. Malignancy-associated hypercalcemia (MAH) signifies advanced disease, with median survival of less than 2 months. Synthesis of PTHrP, classically called humoral hypercalcemia, causes about 80% of cases of MAH, and is usually associated with squamous cancers, such as lung, esophagus, head and neck, cervical, ovarian, and endometrial carcinomas. Presenting symptoms often include weakness, lethargy, confusion, abdominal pain, nausea, vomiting, constipation, polyuria, polydipsia, and kidney injury. Electrocardiogram findings may initially exhibit QT interval shortening, progressing to dysrhythmias and heart block as hypercalcemia worsens.
The treatment of many acid-base derangements requires identification and treatment of the underlying cause. Emergency clinicians should recognize when an acid-base disorder is present and use a systematic approach that incorporates an understanding of the essential elements of acid-base physiology, the most important causes of acid-base derangements, and key steps in their management. Many basic cellular processes are sensitive to small changes in serum pH; the kidneys, lungs, and physiologic buffers determine serum pH, which is normally between 7.36 and 7.44. Serum pH is determined by the relative concentrations of bicarbonate (\(\text{HCO}_3^-\)) and carbon dioxide (\(\text{Paco}_2\)) = \(1.5 \times \text{serum HCO}_3^-\) + \([8 \pm 2]\); when two of these variables are known, the third may be calculated. Most blood gas analyzers measure pH and \(\text{Paco}_2\) and report a calculated \([\text{HCO}_3^-]\). Most laboratories, when they report a serum bicarbonate concentration, are reporting a measured total carbon dioxide concentration, which is the sum of the serum bicarbonate and dissolved carbon dioxide. The dissolved carbon dioxide usually contributes negligibly to total carbon dioxide concentration, but can become significant in patients with hypercapnia.

An acidosis is a process that lowers \(\text{HCO}_3^-\) or raises \(\text{Paco}_2\), creating an acidemia when the serum pH is below 7.36. Conversely, an alkalosis represents a process that raises \(\text{HCO}_3^-\) and/or lowers \(\text{Paco}_2\), creating an alkalemia when the serum pH is above 7.44. The terms acidemia and acidosis are not interchangeable—acidosis or alkalosis describes a process that pushes serum pH down or up respectively; acidemia and alkalemia are descriptors of the serum pH. A patient who is acidic has at least one acidosis but may have two or more acidoses and one or more alkaloses. Patients with a normal serum pH may have acidoses and alkaloses whose net effect is serum neutrality.

Bicarbonate concentration is predominantly regulated by the kidneys; \(\text{Paco}_2\) is primarily regulated by lung ventilation. Diseases that affect kidney function may produce a metabolic acidosis or alkalosis, for which the lungs will try to compensate by decreasing or increasing \(\text{Paco}_2\), respectively. Likewise, pulmonary diseases can cause a respiratory acidosis or alkalosis, for which the kidneys will try to compensate by raising or lowering serum \(\text{HCO}_3^-\), respectively. Severe acidemia or alkalnesia (<6.80 or >7.80) is considered unsustainable and may cause cardiac hypococontractility and irritability, seizures, cerebral edema, and metabolic disturbances such as hyperkalemia and catecholamine resistance. In these cases, empirical therapy may be directed at normalization of serum pH while simultaneously searching for the underlying cause.

A reduced serum bicarbonate concentration defines a metabolic acidosis, which may be the primary disorder or a compensation for a primary respiratory alkalosis. An elevated serum bicarbonate concentration defines a metabolic alkalosis, which may be the primary disorder or a compensation for a primary respiratory acidosis. Likewise, a reduced \(\text{Paco}_2\) represents a respiratory alkalosis, and an elevated \(\text{Paco}_2\) represents a respiratory acidosis. When only a primary disturbance and its corresponding compensation are present, it is described as a simple acid-base disorder. A mixed acid-base disorder exists when more than one primary disturbance occurs simultaneously.

Alterations in serum pH are initially resisted by intracellular and extracellular physiologic buffers, followed by specific responses from the lungs and kidneys. Peripheral and central chemoreceptors adjust pulmonary minute ventilation in response to changes in serum pH. In a primary metabolic acidosis, an increase in minute ventilation lowers \(\text{Paco}_2\) and pushes the serum pH closer to normal. Likewise, a primary metabolic alkalosis leads to a reduction in minute ventilation to elevate \(\text{Paco}_2\).

The kidneys’ response to alterations in serum pH occurs over hours to days. A sustained acidemia promotes renal excretion of \(\text{H}^+\) and retention of \(\text{HCO}_3^-\), whereas alkalemia causes renal \(\text{HCO}_3^-\) excretion and \(\text{H}^+\) retention. The kidney transports hydrogen ions in exchange for potassium, whose serum concentration must also be maintained within tight parameters. This may become clinically important when, for example, correction of alkalnesia is attempted; retention of \(\text{H}^+\) cannot occur unless potassium stores are sufficient to allow urinary \(\text{K}^+\) excretion. Potassium supplementation may therefore be necessary to alkalinize the urine (eg, in heterocyclic antidepressant toxicity).

Often, acid-base disturbances are first identified when the results of laboratory tests ordered to evaluate the patient’s symptoms demonstrate alterations in the bicarbonate level, pH, or \(\text{Paco}_2\). The possibility of an acid-base disorder is suggested by clinical events such as toxic ingestions, severe vomiting, or diarrhea, as well as in patients with diseases primarily affecting the lungs and kidneys. All critically ill patients and all patients being mechanically ventilated should have an assessment of their acid-base status. When an acid-base disturbance is identified or suspected, elucidation of its underlying cause(s) is central to appropriate management. When the cause of an acid-base disturbance is not evident, the emergency evaluation begins with a full history and physical examination and proceeds with targeted laboratory studies.

Simple acid-base disorders are categorized by the serum pH, \(\text{Paco}_2\), and \(\text{HCO}_3^-\) concentrations (Table 116.1). When the primary disturbance is identified, the next step is to determine its cause and whether an appropriate compensation has occurred. An inappropriate compensation suggests that the process underlying the primary disturbance has hindered an appropriate response or that more than one primary disturbance is present. Once the primary disturbance has been identified, simple formulas can be used to calculate an appropriate response. Compensatory
processes generally return pH toward normal, but not to normal and never beyond normal; such an exaggerated “compensation” represents a second primary disorder.

Blood gas and serum chemistry analyses allow the calculation and interpretation of the serum anion gap:

Anion gap = Na⁺ − (Cl⁻ + HCO₃⁻)

Plasma must remain electrically neutral: the sum of anions and cations (measured or unmeasured) must be equal. The higher the anion gap, the more likely that one or more unmeasured anions is generating a metabolic acidosis. Because routinely measured cations exceed routinely measured anions, the anion gap represents the concentration of anions other than chloride and bicarbonate in the blood. A variety of these anions are normally present, but serum albumin accounts for most of the physiologic (normal) anion gap, usually between 9 and 15. The impact of albumin can be factored into the anion gap equation by multiplying the reported albumin concentration (g/dL) by 2.5:

\[ \text{Albumin corrected anion gap} = \text{anion gap} + 2.5 \times \left( \text{normal albumin} - \text{measured albumin} \right) \]

Correction for albumin is important because significant depression of the serum albumin level will reduce the anion gap, potentially masking the presence of an important unmeasured anion. For example, a chronically malnourished alcoholic may present with alcoholic ketoacidosis but may also have longstanding hypoalbuminemia, which causes a substantial increase in the serum bicarbonate concentration. An acute ketonemia will reduce the serum bicarbonate level to normal, resulting in no anion gap. Patients at risk for hypoalbuminemia who present with significant illness should have their serum albumin level measured. In these patients, if albumin is low, a normal serum bicarbonate concentration represents a metabolic acidosis.

In addition to albumin, classic unmeasured anions such as lactate and ketones can also be measured and incorporated into a diagnostic pathway. For example, a lactate level of 4 mEq/L can be presumed to account for an anion gap of 16 mEq/L, but not an anion gap of 25 mEq/L; in this case, other unmeasured anions should be sought. Unmeasured cations are also present and may account for an elevated anion gap in a case of hypomagnesemia or hypocalcemia, often in combination with hypokalemia; because the serum potassium concentration varies so little, it is usually left out of anion gap calculations and is therefore functionally an unmeasured cation. Elevated concentrations of unmeasured cations may cause a low anion gap (<3 mEq/L), such as in cases of lithium toxicity and hypergammaglobulinemia seen in multiple myeloma. Bromide toxicity may cause spurious hyperchloremia, and hypertriglyceridemia may cause spurious hyponatremia, which can also cause a low or negative anion gap. Overall, a normal anion gap does not exclude clinically significant acidosis or high concentrations of unmeasured anions. Direct measurement of compounds that often produce an elevated anion gap (eg, lactate, ketones, toxic alcohols) should still be pursued when there is clinical concern, despite a normal anion gap.

Independent of bicarbonate levels, sodium and chloride play an important role in acid-base status. When the strong ion difference ([Na⁺ + K⁺] − [Cl⁻]) is significantly less than 40, an acidosis is present. An alternative to using the anion gap to identify the presence and cause of acid-base disorders begins with the base excess, which can also cause a low or negative anion gap. Overall, a normal anion gap does not exclude clinically significant acidosis, the unmeasured anions (eg, lactate, ketones, uremic acids, toxic alcohols, other toxins).

Unmeasured anions = base excess red anion − [Cl⁻] − 38
− 2.5 × (4.2 − [measured albumin])

This physicochemical (Stewart) approach may identify acid-base derangements with more sensitivity than the conventional anion gap, although the clinical relevance of metabolic abnormalities occult to bicarbonate-centered calculations is uncertain. Some have suggested integrating principles of the two approaches, whereas others have questioned the value of the physicochemical method in clinical practice. Using the classic anion gap to identify acid-base disorders is appropriate in most emergency scenarios, especially if the lactate and albumin levels are measured and incorporated.

Painful arterial blood sampling is unnecessary for the evaluation of acid-base disturbances. Paco₂, HCO₃⁻, and pH values taken from peripheral venous, central venous, inratroous, and capillary blood are all suitable for acid-base assessment.

### SPECIFIC ACID-BASE DISORDERS

#### Respiratory Acidosis

Respiratory acidosis occurs when hypoventilation leads to an inappropriately elevated Paco₂ and resulting acidemia. Any condition that reduces minute ventilation may cause respiratory acidosis (Box 116.1). This commonly occurs acutely in the setting of airway compromise, pulmonary insults, major trauma, intracranial catastrophe, and central nervous system (CNS) depressants; it occurs chronically in progressive lung disease, neurologic muscle weakness, and obesity hypoventilation syndrome. Respiratory acidosis may be accompanied by hypoxemia, which, depending on its pace and severity, will cause end-organ effects such as headache, ischemic chest pain, altered mental status (usually agitation), bradycardia, and circulatory collapse. Hypercapnia is better tolerated than hypoxemia; when tissue oxygenation is adequate, hypercapnia will tend to produce somnolence and obtundation, with cerebral vasodilation and resulting elevation of intracranial pressure.

Beginning 6 to 12 hours after onset and progressing for 3 to 5 days, the kidneys respond to a respiratory acidosis by retaining bicarbonate. The resulting compensatory metabolic alkalosis, with an elevated serum bicarbonate level, partially corrects serum pH. Because chloride ions are excreted in the urine to increase the serum HCO₃⁻, patients with chronic respiratory acidosis (eg, as seen in chronic obstructive pulmonary disease) are often noted to

---

*aSodium chloride effect = [Na⁺] − [Cl⁻] − 38.

*bAluminum effect = 2.5(4.2 − [albumin]).
have hypocloremia. An appropriate metabolic compensation for respiratory acidosis is an increase of approximately 3.5 mEq/L in the serum HCO₃⁻ concentration for every increase of 10 mm Hg in PaCO₂. A patient with chronic respiratory disease resulting in a baseline PaCO₂ of 60 mm Hg would therefore be expected to have a serum bicarbonate level of approximately 30 mEq/L and a slight acidemia, because without another primary acid-base abnormality, correction is never to a normal pH.

Acute respiratory acidosis is the most immediately dangerous of the acid–base disturbances. Relief of airway obstruction and provision of noninvasive or mechanical ventilation will often correct imminently dangerous hypoxemia or hypercapnia as therapy directed at the underlying disorder is initiated.

Patients with chronic respiratory acidosis are often hypoxemic at baseline and may be susceptible to further hypoventilation if normal oxygen saturation levels are promptly restored. Typically, a patient with chronic obstructive pulmonary disease being treated for an acute exacerbation receives high-flow oxygen and is later found to be obtunded, with profound hypercapnia. The chronic respiratory acidosis results in a respiratory drive that is more dependent on Po₂ than PaCO₂ levels. When high-flow oxygen is applied, the respiratory drive is suppressed, and PaCO₂ further increases, leading to somnolence and eventually apnea. It is therefore prudent to target a lower than normal oxygen saturation in patients thought to be so habituated; SpO₂ fractions in the low 90s and high 80s are usually well tolerated in this population.

However, supplemental oxygen must not be withheld from patients with dangerously low oxygen saturation (SpO₂ in the 70s or less) or patients with end-organ hypoxic dysfunction, such as myocardial or cerebral ischemia. In these cases, aggressive oxygenation therapies should be instituted, preferably in combination with noninvasive ventilator support, with preparations made for mechanical ventilation, if needed. Standard ventilator settings applied to patients who chronically hypoventilate may precipitate posthypercapnic metabolic alkalosis. Clinicians should target a slightly acidemic serum pH (≈7.35), which, depending on the severity and chronicity of the patient’s baseline respiratory acidosis, may correspond to remarkably high PaCO₂ levels.

Respiratory Alkalosis

Respiratory alkalosis occurs when increased minute ventilation causes a decreased PaCO₂ and subsequent increase in the serum pH. Although commonly associated with anxiety-related hyperventilation, the emergency clinician should consider medical conditions before arriving at a psychiatric diagnosis (Box 116.2).

An important cause of acute respiratory alkalosis is salicylate toxicity, a dangerous, treatable mixed acid–base disorder (described later) that may manifest with hyperventilation. Suicidal aspirin ingestions often produce the classic syndrome of tinnitus, hyperthermia, confusion, and a variety of metabolic derangements, ultimately leading to seizures, coma, and cardiovascular collapse. Chronic salicylism, however, is notoriously subtle in its presentation and occurs in older sicker patients who seemingly have more likely explanations for their symptoms. Salicylate toxicity should be strongly considered in these patients, as well as those with an unexplained respiratory alkalosis.

Blood pH alters the binding affinity of calcium for albumin. When the pH lowers, calcium loses some affinity for albumin (increasing free calcium); when the pH increases, calcium binds more strongly to albumin (decreasing free calcium). Thus, clinical features of respiratory alkalosis include those from hypocalcemia—lip and extremity paresthesias, carpal pedal spasm, muscle cramps, lightheadedness, and syncope. The homeostatic response to respiratory alkalosis first involves cellular secretion of H⁺ in exchange for K⁺; if respiratory alkalosis persists, the kidneys excrete bicarbonate and retain chloride, leading to a compensatory metabolic acidosis, with reduced serum HCO₃⁻, hypokalemia, and hyperchloremia.
Pregnant women hyperventilate throughout gestation and normally have a PaCO₂ between 31 and 35 mm Hg, serum pH between 7.46 and 7.50, and serum bicarbonate concentration between 18 and 22 mEq/L. Thus, eucapnia (PaCO₂ ≅ 40 mm Hg) may represent hypoventilation in pregnant patients.

As with other acid-base disorders, the management of respiratory alkalosis should be directed at the underlying cause. When organic causes of respiratory alkalosis have been excluded, hyperventilation by reassurance. The technique of using a paper bag to cause rebreathing probably works through the placebo effect rather than by changes in PaCO₂ but carries the potential danger of inducing hypoxemia.

**Metabolic Acidosis**

Metabolic acidosis, defined by a reduced serum bicarbonate concentration, occurs when acids are added by intrinsic processes or from exogenous sources, acid excretion is impaired, or there is inappropriate loss of alkali. Metabolic acids are classically divided into normal anion gap and elevated anion gap to assist in determining their causes.

**Elevated Anion Gap Metabolic Acidosis**

Common unmeasured anions that cause an elevated anion gap include lactate, keto acids (usually from diabetic ketoacidosis), acidic products of exogenous toxins (eg, the toxic alcohols), and organic acids that accumulate in renal failure. The causes of elevated anion gap metabolic acidosis are classically remembered by the mnemonic MUDPILES; however, it is more useful to focus on the identity of the unmeasured anion (Box 116.3). For example, if the cause of an elevated anion gap metabolic acidosis is found to be lactate or ketones, the next step is to determine the cause of lactatemia or ketonemia.

**Lactic Acidosis.** Increased production of lactate is a common cause of elevated anion gap metabolic acidosis, and the serum lactate level should be measured whenever another cause is not apparent. Because of the coincident acid-base disturbances that may be present in patients with a high serum lactate level, a normal anion gap does not exclude clinically important lactic acidosis. Causes of lactic acidosis can be divided into hypoxic or from exogenous sources, acid excretion is impaired, or there is inappropriate loss of alkali. Metabolic acidosis are classically divided into normal anion gap and elevated anion gap to assist in determining their causes.

**Severe Rhabdomyolysis**

Diabetic Ketoacidosis. Diabetic ketoacidosis (DKA) is a common acid-base disorder defined by hyperglycemia, ketonemia, and acidemia. Patients with DKA classically complain of progressive polyuria, polydipsia, and malaise, but DKA may be manifested atypically with chief complaints of vomiting, abdominal pain, and/or altered mental status. Sodium concentration is not corrected for hyperglycemia in the anion gap calculation because this dilutional effect influences other ions in the calculation as well. DKA is often caused by medication noncompliance, but may complicate any physiologic stress; when DKA is diagnosed, identification of the precipitant is a management priority. Treatment of DKA focuses on volume expansion with IV fluids, insulin therapy, and careful attention to and replacement of electrolytes, particularly potassium. (For more detail, see Chapter 115.)

Alcoholic Ketoacidosis. Alcoholic ketoacidosis (AKA) causes an elevated anion gap metabolic acidosis that may be mistaken for DKA. AKA can occur when a long-standing ethanol user abruptly stops drinking; ketones are generated by a combination of malnutrition and dehydration. Patients with AKA may demonstrate a high anion gap, but a mixed acid-base disorder may be present due to concomitant ethanol withdrawal, which...
may cause a respiratory alkalosis and metabolic alkalosis from vomiting. A result, the serum pH can be acidemic, normal, or alkaline. Like DKA, AKA includes the symptoms of vomiting, abdominal pain, dehydration, altered mental status, prostration, and lethargy; however, AKA patients generally do not demonstrate hyperglycemia or glycosuria. In AKA, the ratio of the keto acid $\beta$-hydroxybutyrate to its metabolites acetoacetate and acetone is double the ratio seen in DKA because metabolites of alcohol cause a reduction of acetoacetate to $\beta$-hydroxybutyrate. A urine dipstick can detect acetoacetate but not $\beta$-hydroxybutyrate; this causes an apparent worsening ketonuria as the patient metabolizes $\beta$-hydroxybutyrate to acetoacetate, although the patient is actually recovering. The treatment of AKA is dextrose-containing fluids; insulin is contraindicated. (For more detail, see Chapter 141.)

Methanol and Ethylene Glycol. The toxic alcohols, methanol and ethylene glycol, represent important potential causes of an elevated anion gap metabolic acidosis. There considerable morbidity and mortality can be prevented by timely therapy, and the presence of a wide anion gap may be the most conspicuous sign of these dangerous ingestions. Toxic alcohols are typically consumed by alcoholics seeking a less expensive drink, by children as an accidental ingestion (usually ethylene glycol, which is sweet), or in a suicide attempt. The first measurable sign of toxic alcohol poisoning is an osmol gap, which precedes an elevated anion gap. As the parent compounds are converted to their toxic metabolites, the osmol gap closes, and the anion gap widens. Treatment centers on prevention of the enzymatic conversion of methanol and ethylene glycol into their toxic metabolites by the use of ethanol or fomepizole. Many laboratories will report a spuriously elevated lactate concentration in the presence of glycolate, a byproduct of ethylene glycol poisoning. Isopropyl (rubbing) alcohol ingestion causes intoxication, ketosis, and an osmol gap but does not cause acidosis. (For more detail, see Chapter 141.)

Renal Failure. The body normally generates a net acid load that the kidneys must continuously excrete. Any condition that reduces the glomerular filtration rate will undermine this function, and unmeasured anions such as sulfate, phosphate, urate, and hippurate will generate an elevated anion gap metabolic acidosis. In chronic renal failure, patients with uremia-associated metabolic acidosis may receive sodium bicarbonate or sodium citrate as a bridge to renal replacement therapy. In acute renal failure causing metabolic acidosis, sodium bicarbonate can temporarily acidify the patient can be dialyzed. Health care providers should be cautious in patients with oliguria or volume overload because sodium bicarbonate may deliver a hemodynamically significant volume load. (For more detail, see Chapter 87.)

Isoniazid Toxicity. Isoniazid (INH) toxicity is usually listed in the differential for metabolic acidosis, but consideration of INH toxicity should primarily be prompted by intractable seizures. It is the seizures that cause the lactic acidosis, not INH directly. INH toxicity is an important consideration in these cases because it causes seizures that do not respond to usual treatments. Continuous seizure activity, in addition to cardiorespiratory compromise, causes a profound, life-threatening acidemia from lactic generation. The initial treatment of status epilepticus related to INH toxicity is the administration of vitamin B₆ (pyridoxine). Specific therapies targeting nonepileptic causes of seizures, such as hypoglycemia, eclampsia, hyponatremia, and cyanide toxicity, should also be considered in the patient with seizures unresponsive to standard therapy.

Salicylate Toxicity. Salicylate toxicity first produces a respiratory alkalosis, as previously described. Untreated, the syndrome evolves into a complex acid-base disorder with paradoxical aciduria during the initial respiratory alkalosis, followed by an elevated anion gap metabolic acidosis and hyperthermia due to its interference with cellular metabolism. The serum pH can be normal during the initial phase of the disease, a false reassurance. Dehydration, electrolyte disturbances, fatigue, and lung injury ultimately lead to decompensation with respiratory acidosis—completing the so-called triple acid-base disturbance—followed by cardiovascular collapse. Management of aspirin toxicity includes gastrointestinal decontamination, urine alkalization, meticulous supportive care, and hemodialysis. (For more detail, see Chapter 144.)

Iron Ingestion. Iron ingestion is a dangerous cause of metabolic acidosis that presents with gastric irritation causing prominent vomiting and other gastrointestinal symptoms. This phase is followed by one of systemic toxicity—myocardial depression, liver injury, and lactic acidosis from cellular mitochondrial poisoning. A plain radiograph of the abdomen may provide evidence of an iron ingestion while the serum iron concentration is determined. Treatment measures include fluid resuscitation, gastrointestinal decontamination, and chelation with deferoxamine. (For more detail, see Chapter 151.)

Normal Anion Gap Metabolic Acidosis

Normal anion gap metabolic acidosis is less likely to be immediately dangerous or caused by an imminently dangerous condition. Most cases encountered in the emergency department (ED) are caused by gastric loss of bicarbonate in the setting of diarrhea. A variety of other conditions and medications may cause a normal anion gap metabolic acidosis (Box 116.4), including renal tubular acidosis and bladder-diverting urologic procedures. A common iatrogenic cause of normal anion gap metabolic acidosis is the rapid infusion of large volumes of normal saline, which contains 154 mEq/L of sodium and chloride without bicarbonate or any

### BOX 116.4

#### Causes of Normal Anion Gap Metabolic Acidosis

**GASTROINTESTINAL HCO₃⁻ LOSS**
- Diarrhea
- Colostomy or ileostomy
- Enteric fistulas
- Ion exchange resins (e.g., sodium polystyrene sulfonate [Kayexalate])

**RENAK HCO₃⁻ LOSS**
- Renal tubular acidosis
- Tubulointerstitial renal disease
- Hyperparathyroidism

**RAPID NORMAL SALINE INFUSION**
- Urologic procedures
- Ureterosigmoidostomy
- Ureterosigmoidoscopy

**INGESTIONS**
- Acetazolamide
- Calcium chloride (CaCl₂)
- Magnesium sulfate (MgSO₄)

**OTHER**
- Hypoadosteronism
- Hyperkalemia
- Toluene (after initial elevated anion gap metabolic acidosis)
other buffer and is therefore acidic compared to serum. The hyperchloremic acidosis associated with normal saline therapy is generally well tolerated. Intensive care unit (ICU) studies comparing chloride-liberal and chloride-restrictive fluid strategies have been observational; however, consensus currently favors isotonic, physiologic crystalloid only. Although 1 to 2 L of normal saline is likely inconsequential compared to other fluid preparations, patients requiring large-volume resuscitation, particularly when accompanied by acidemia, hyperkalemia, or kidney injury, should receive a balanced fluid (e.g., lactated Ringer’s solution, Normosol, Plasma-Lyte).

Physiologic Compensation for Metabolic Acidosis

Immediate physiologic compensation for a metabolic acidosis occurs via the extracellular bicarbonate–carbonic acid system and intracellular protein buffers. Medullary chemoreceptors augment alveolar ventilation to blow off carbon dioxide, partially correcting the serum pH. In severe metabolic acidosis (pH < 7.1), hyperventilation is profound and assumes the appearance of Kussmaul’s respirations, in which hyperpnea (increased tidal volume) is seen out of proportion to tachypnea (increased respiratory rate). In cases of prolonged metabolic acidosis, the kidney generates a compensatory aciduria by secreting H⁺ and retaining HCO₃⁻.

Metabolic Alkalosis

Metabolic alkalosis occurs from loss of H⁺ or retention of HCO₃⁻. It is usually a consequence of prolonged vomiting or nasogastric suction or a compensation for chronic respiratory acidosis. The differential diagnosis includes a variety of predominantly endocrine and electrolyte disorders (Box 116.5). Patients taking diuretic medications may reduce their plasma volume around a steady state concentration of HCO₃⁻, causing a contraction alkalosis. Contraction alkalosis often presents with hypokalemia, which itself causes a metabolic alkalosis as intracellular K⁺ is exchanged for extracellular H⁺.

In the acute phase, the lungs compensate for a metabolic alkalosis by decreasing minute ventilation and retaining carbon dioxide; the PaCO₂ should increase by approximately 0.7 mm Hg for every 1-mEq/L increase in serum HCO₃⁻. (Of note, hypoventilation should be assumed to be a more dangerous primary respiratory disorder until proven otherwise.) Prolonged metabolic alkalosis leads to compensatory renal HCO₃⁻ excretion.

DIAGNOSTIC TESTING AND MIXED DISORDERS

A simple acid-base disorder is a combination of a primary disturbance and subsequent compensation. Mixed acid–base disorders occur when two or more primary acid–base lesions coincide. These simultaneous conditions may push the serum pH in the same or opposite direction, and each will generate its own compensatory responses; mixed disorders may therefore be difficult to recognize by clinical or laboratory features. In ED patients with mixed acid–base disorders, there is commonly a dominant precipitating problem that complicates an existing disease or causes failure of compensatory mechanisms.

The body usually does not fully compensate for a primary acid–base disorder so, for example, a primary metabolic acidosis should generate a compensatory respiratory alkalosis, but the serum pH is expected to still be below 7.36. Whether an appropriate respiratory compensation to a metabolic acidosis has occurred can be approximated by comparing the Pao₂ to the last two digits of the serum pH. In a primary metabolic acidosis with appropriate respiratory compensation, these two values should be similar; that is, a patient with a serum pH of 7.20 should have a Pao₂ of 20 mm Hg. If the serum pH is 7.17 and the Paco₂ is 30 mm Hg, the respiratory compensation is less than expected and a primary respiratory acidosis is present. This is commonly seen in patients whose dominant condition causes a metabolic acidosis but also impairs respiration, such as sepsis.

The delta gap (DG) describes the difference between the deviation of the anion gap (AG) from normal and the deviation of the serum bicarbonate concentration from normal:

\[
DG = (AG - 12) - (24 - [HCO₃⁻])
\]

Conceptually, calculation of the delta gap tried to determine whether the anion gap is accounted for by the change in serum bicarbonate concentration. In patients with an elevated anion gap and a delta gap greater than +6, meaning that the serum bicarbonate level is significantly higher than would be predicted by the number of unmeasured anions, a metabolic acidosis in addition to a metabolic acidosis is likely to be present. This is commonly seen when the dominant acidosis condition causes severe vomiting (e.g., diabetic ketoacidosis). In patients with an elevated anion gap and a delta gap more negative than −6, meaning that the serum bicarbonate level is significantly lower than expected given the anion gap, a normal anion gap metabolic acidosis is likely to be present in addition to the elevated anion gap metabolic acidosis. This is usually seen when a lactic acidosis complicates severe diarrhea.

MANAGEMENT

Acidosis

Management of metabolic acidosis is directed at identification and treatment of the underlying cause while appropriate resuscitative and supportive care are provided. An example of this paradigm is the management of generalized seizures; seizures often cause profound acidemia but, if terminated promptly, the serum pH normalizes quickly and without sequelae.

The role of IV sodium bicarbonate in the treatment of acidaemia is controversial. Theoretic harms include the following:

- Paradoxical CNS acidosis—because sodium bicarbonate does not readily cross the blood-brain barrier, serum alkalinizes much faster than the cerebrospinal fluid. As the serum pH
In summary, sodium bicarbonate should not routinely be used to treat undifferentiated acidemia or acidemia caused by lactic acidosis or ketoacidosis. If the serum pH is so severely depressed that the acidemia itself is thought to be an immediate life threat, bicarbonate therapy is an option. A lower treatment threshold is appropriate in acidemia caused by bicarbonate loss or renal failure, and bicarbonate should not be withheld when it is specifically indicated to treat the underlying cause of an acidosis.

Acidemia causes hyperkalemia as $H^+$ is brought into cells in exchange for $K^+$. Emergency clinicians managing patients with acid-base disturbances should carefully monitor the serum potassium concentration; as the acidosis resolves, the serum potassium level will fall and may require supplementation. This is classically seen in DKA patients, who are invariably potassium-depleted, irrespective of their initial serum potassium concentration.

### Alkalosis

Metabolic alkalosis rarely causes dangerous alkalasia, so the management of metabolic alkalosis is directed at the identification and treatment of dangerous underlying causes. IV fluids and electrolyte replacement for patients with volume loss, vomiting, or hypokalemia will address the resulting saline-responsive metabolic alkalosis. Edematous or euvoletic patients with conditions that cause renal Na$^+$ retention—and accompanying H$^+$ loss—may have a saline-resistant metabolic alkalosis, but this generally does not require emergency therapy. In rare cases, severe metabolic alkalosis may cause hypocalcemic tetany, seizures, altered mental status, or dysrhythmias and require emergent empirical therapy, usually in consultation with nephrology, with acetazolamide or hydrochloric acid.

### Key Concepts

- Patients with an acute severe metabolic acidosis rely on a robust respiratory compensation; in these cases, the adequacy of the ventilatory response should be assessed and augmented, with noninvasive or invasive ventilation, if needed.
- The strong ion difference ($\Delta$) = $(Na^+ + K^+) - [Cl^-]$. When significantly less than 40, an acidosis is present.
- The delta gap ($\Delta G$) = $(AG - 12) - (24 - [HCO_3^-])$. Its calculation determines if the anion gap is accounted for by the change in serum bicarbonate concentration. An elevated anion gap and $\Delta G$ more than 6 indicates that a metabolic alkalosis in addition to a metabolic acidosis is likely to be present.
- Patients who have a chronic respiratory acidosis (eg, in chronic obstructive pulmonary disease) are at risk for dangerous alkalasia if they are ventilated with routine parameters. Blood gas analysis in these cases should be performed frequently and settings titrated to the serum pH.
- Alcoholic ketoacidosis may be manifested similarly to diabetic ketoacidosis but is much less common; insulin is contraindicated in alcoholic ketoacidosis.
- When an elevated anion gap is recognized, the initial assessment focuses on identifying one of four causes: ketoacidosis, toxic ingestions, lactic acidosis, and renal failure. Typically, only chronic renal failure causes significant acidosis.
- Anion gap = Na$^+$ – (Cl$^-$ + HCO$^-_3$). Causes of an elevated anion gap include ketoacidosis, lactic acidosis, toxins metabolized to acids, and renal failure.
- When the cause of an elevated anion gap is determined to be lactate or ketones, diagnostic efforts are directed at identifying the cause of the lactic acidosis or ketoacidosis.
- Sodium bicarbonate is not recommended for the empirical treatment of acidemia; it is an option in cases of severely depressed pH thought to pose an immediate life threat.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
3 and P

Chronic diarrhea is the most common cause. Hypoalbuminemia would be such a case. This patient has an anion gap of 3. Because the anion gap is due to unmeasured anions such as albumin, sulfate, phosphate, and citrate, isolated depressions of these may cause a low anion gap. Hypoalbuminemia would be such a case.

What is the most common cause of normal anion gap metabolic acidosis?
A. Acetazolamide use
B. Diarrhea
C. Hypoaldosteronism
D. Magnesium sulfate
E. Renal tubular acidosis

Answer: B. Chronic diarrhea is the most common cause.

A 31-year-old man has the following laboratory values:
- Sodium = 142 mEq/L
- Potassium = 3.8 mEq/L
- Chloride = 110 mEq/L
- Bicarbonate = 29 mEq/L
- Creatinine = 1.0 mg/dL
- CO2 levels.

Which of the following is true?
A. He may have a low albumin level.
B. Ionized calcium will be low.
C. Organic acid ingestion should be considered.
D. The blood glucose level is likely elevated.
E. The serum lactate level will be elevated.

Answer: A. This patient has an anion gap of 3. Because the anion gap is due to unmeasured anions such as albumin, sulfate, phosphate, and citrate, isolated depressions of these may cause a low anion gap. Hypoalbuminemia would be such a case.

A 31-year-old man has the following laboratory values:
- Sodium = 142 mEq/L
- Potassium = 3 mEq/L
- Chloride = 90 mEq/L
- HCO3− = 30 mEq/L
- Glucose = 140 mg/dL
- Urinalysis = specific gravity (SG) 1.024 and trace ketones
- Which of the following is true?
A. A chest CT is indicated.
B. Crystalloid alone will correct the abnormalities.
C. His urinary ketone levels will increase with treatment.
D. Insulin infusion is indicated.
E. The pH is appropriate for the HCO3− and Pco2 levels.

Answer: C. Alcoholic ketoacidosis (AKA) usually presents after abrupt alcohol intake cessation following a binge. Ketoacidosis, malnutrition, and dehydration all coexist. Urine ketone levels may be minimal due to the lack of detection of e hydroxybutyrate, prominent in AKA. This is later converted to acetoacetate and acetone, transiently worsening the ketosis while improving the ketoacidosis during treatment. Measurement of urine ketone levels can therefore produce paradoxical results. Dextrose-containing fluids are the mainstay of treatment; insulin is contra-indicated. This patient has a complex acid-base disorder with a combination of an anion gap acidosis caused by AKA, with secondary respiratory alkalosis and primary metabolic alkalosis from vomiting.

How does isoniazid (INH) cause a metabolic acidosis?
A. INH acts as a cellular toxin by uncoupling oxidative phosphorylation.
B. INH causes bicarbonate wasting at the level of the glomerulus.
C. INH causes increased lactic acid production by liver toxicity.
D. INH is acidic and lowers serum pH directly.
E. INH overdose causes seizures, which lead to a metabolic acidosis.

Answer: E. Isoniazid overdose is an important cause of seizures, especially seizures that are unresponsive to conventional therapies. Treatment of INH-induced seizures is vitamin B6 (pyridoxine).
116.5. A 26-year-old G3P2 woman at 32 weeks of gestation presents with mild dyspnea on exertion for several weeks. She has no pain and no other complaints. Physical examination is remarkable only for a RR of 26 breaths per minute. Arterial blood gas reveals the following:

- \( P_{O_2} = 98 \text{ mm Hg} \)
- \( P_{CO_2} = 32 \text{ mm Hg} \)
- \( pH = 7.49 \)
- \( HCO_3^- = 19 \text{ mEq/L} \)

The complete blood count, electrocardiogram, and chest radiograph with shielding are normal. Which of the following is true?

A. No intervention is indicated.
B. Salicylate levels are indicated.
C. Serum lactate level will be helpful.
D. There is an underlying metabolic acidosis.
E. Ventilation-perfusion scan is indicated.

Answer: A. Alkalemia of pregnancy occurs early and is sustained throughout gestation. A \( P_{CO_2} \) of 31 to 35 mm Hg with a compensatory drop in serum \( HCO_3^- \) is normal. The \( pH \) ranges from 7.46 to 7.50. All these values are normal for pregnancy.

116.6. A patient with severe, long-standing chronic obstructive pulmonary disease presents in respiratory distress and requires endotracheal intubation. Blood gas analysis 20 minutes later shows the following:

- \( pH = 7.55 \)
- \( P_{O_2} = 140 \text{ mm Hg} \)
- \( P_{CO_2} = 37 \text{ mm Hg} \)
- \( HCO_3^- = 44 \text{ mEq/L} \)

What is the likely explanation for these results?

A. The patient has a chronically elevated serum bicarbonate level.
B. The patient has coexisting hypoalbuminemia.
C. The patient is receiving too much supplemental oxygen.
D. The patient received supplemental bicarbonate therapy.

Answer: A. Patients with long-standing respiratory acidosis develop a compensatory metabolic alkalosis with an elevated serum bicarbonate level. When these patients are mechanically intubated, minute ventilation should be reduced compared with normal patients and should be titrated to \( pH \).

116.7. An older patient presents with altered mental status without a clear cause after a history and physical examination. Blood gas analysis shows the following:

- \( pH = 7.44 \)
- \( P_{O_2} = 94 \text{ mm Hg} \)
- \( P_{CO_2} = 19 \text{ mm Hg} \)
- \( HCO_3^- = 21 \text{ mEq/L} \)

These results should prompt consideration of which cause of altered mental status?

A. Acute coronary syndrome
B. Intracranial hemorrhage
C. Salicylate toxicity
D. Urosepsis

Answer: C. Chronic salicylate toxicity is an important concern in older patients, and an unexplained respiratory alkalosis may be the most important presenting finding. A history targeting long-standing salicylate use and measurement of the serum salicylate level are appropriate next steps.

116.8. A patient presents with diabetic ketoacidosis. The initial blood gas shows a serum \( pH \) of 7.05. Resuscitation with normal saline can cause which acid-base disturbance?

A. Metabolic acidosis
B. Metabolic alkalosis
C. Respiratory acidosis
D. Respiratory alkalosis

Answer: A. Because normal saline is acidic compared with serum, use can cause a non–anion gap hyperchloremic metabolic acidosis. Although this type of acidosis is generally well tolerated, if the serum \( pH \) is severely depressed, switching to a more balanced electrolyte solution may be prudent.

116.9. In which case should sodium bicarbonate be used?

A. A patient in cardiac arrest of uncertain cause
B. A patient pulled from a fire thought to be exposed to cyanide
C. A patient with heterocyclic antidepressant overdose
D. A patient with sepsis, lactic acidosis, and serum \( pH \) of 6.9

Answer: C. Sodium bicarbonate as an empirical treatment for acidemia or undifferentiated cardiac arrest is not recommended; however, sodium bicarbonate should be administered when indicated as a specific therapy, such as in certain toxic ingestions.
Electrolyte abnormalities are common in emergency medicine and can vary greatly in importance, severity, and symptoms. Asymptomatic electrolyte abnormalities can be gradually corrected, whereas those causing alterations in consciousness or life-threatening dysrhythmias require immediate therapy to avoid permanent sequelae or death. In some cases, therapy for life-threatening electrolyte disorders may precede laboratory confirmation.

**HYPERKALEMIA**

**Principles**

Hyperkalemia, defined as serum potassium level greater than 5.0 mEq/L, is the most dangerous acute electrolyte abnormality, potentially leading to life-threatening arrhythmias and death. Although hyperkalemia may have vague and varied symptoms, it is usually totally asymptomatic and can present with cardiac arrest as its first “symptom.” Serum potassium concentration is normally between 3.5 and 5.0 mEq/L and is tightly regulated by the kidneys. Hyperkalemia usually develops from impaired renal excretion or intracellular release; however, in advanced chronic kidney disease or end-stage renal disease, dietary intake of potassium may be a significant factor in its development. Risk factors for hyperkalemia include impaired potassium excretion, such as dehydration and renal failure, as well as medications that cause potassium retention. Evaluation of the 12-lead electrocardiogram (ECG) of patients at risk for this electrolyte disturbance helps steer management decisions. Hyperkalemia can be rapidly progressive, requiring lifesaving interventions at the earliest suspicion of toxicity.

Hyperkalemia causes cardiotoxicity by increasing the resting membrane potential of the cardiac myocyte, causing “membrane excitability,” and conversely, sluggish depolarization, as well as decreased duration of repolarization. At very high levels, potassium causes the depolarization threshold to rise, leading to overall depressed cardiac function. Nearly any cardiac arrhythmia can be seen with hyperkalemia, including heart blocks, bradydysrhythmias, pseudoinfarction ST-segment elevation, Brugada pattern, and the classic “sine wave” pattern. As hyperkalemia advances, the end result is cardiac arrest, usually from disintegration into ventricular fibrillation, pulseless electrical activity, or asystole. A serum potassium level of 10.0 mEq/L is usually fatal, but compensation and death can occur at any level above 7 to 8 mEq/L.

The most common cause of hyperkalemia is spurious elevation due to hemolysis during or after the blood draw. Thus, an ECG should be used to assess for true hyperkalemia while another sample is analyzed. Box 117.1 organizes the most common causes of hyperkalemia. The presence of one of these conditions may be the lone historical clue in hyperkalemia.

**Clinical Features**

Hyperkalemia is a difficult diagnosis to make on clinical grounds alone. Hyperkalemia is classified as mild (K 5.5 to 6.0), moderate (K 6.1 to 6.9) or severe (K >7.0). Patients with mild to moderate hyperkalemia are often identified during routine blood sampling for an unrelated condition. Patients with moderate to severe hyperkalemia may have gastrointestinal effects, such as nausea, vomiting, and diarrhea, which are often associated with their underlying disease. Patients with severe hyperkalemia may present with neuromuscular findings, including muscle cramps, generalized weakness, paresthesias, tetry, and focal or global paralysis. The signs and symptoms of progressive muscle weakness, paresthesias, dyspnea, and depressed deep tendon reflexes are neither sensitive nor specific, nor do they appear reliably with a particular serum potassium level. Patients with severe hyperkalemia may present with hemodynamic instability and cardiac arrhythmias requiring immediate intervention.

**Diagnostic Strategies**

The ECG is helpful in making the diagnosis of hyperkalemia and can be used in unstable patients to initiate treatment (Figs. 117.1 to 117.3). Classic electrocardiographic changes—the peaked T wave, flattened p wave with prolonged PR interval or a totally absent P wave, wide QRS, and sine wave pattern, portending imminent cardiac arrest—have been well described as appearing sequentially with rising serum potassium levels. Peaked T waves usually appear as serum potassium levels exceed 5.5 to 6.5 mEq/L; P wave disappearance and PR prolongation are common with levels above 6.5 to 7.5 mEq/L; and levels above 7.0 to 8.0 mEq/L can result in QRS prolongation. Although these changes may occur in only half the patients, recognition of these patterns is vital to rapid diagnosis and initiation of lifesaving treatment. A serum potassium level above 5.0 mEq/L is diagnostic of hyperkalemia, but the value itself does not always predict electrocardiographic changes or the degree of cardiotoxicity. Furthermore, stable patients who are otherwise unlikely to have elevated potassium should not be presumptively treated for hyperkalemia based on subtle electrocardiographic changes alone. When correcting severe hyperkalemia, atrial flutter cycle length can shorten, progressing to atrial fibrillation as the atria become more excitable. In addition, hyperkalemia may present as an atropine resistant bradycardia, with or without apparent heart block.

**Management**

Patients with suspected or known hyperkalemia should have intravenous (IV) access and continuous cardiac monitoring. Treatment of hyperkalemia should be directed by the clinical scenario combined with the ECG and laboratory potassium value, and consists of three main steps: (1) stabilization of the cardiac membrane, (2) shifting of potassium into the cells, and (3) removal of potassium from the body. A variety of treatment options are considered for the acute management of hyperkalemia, including calcium, insulin, beta-agonists, sodium bicarbonate, resins, and dialysis (Table 117.1).

IV calcium stabilizes the cardiac membrane by restoring the electrical gradient. Calcium increases the depolarization threshold and the calcium gradient across the cardiac membrane, quieting
preferably administered through a central venous line due to the risk of tissue necrosis should it extravasate at the injection site. More than 10 mL of calcium gluconate will often be required, because it contains only one-third the calcium contained in calcium chloride. Calcium gluconate is preferred in pediatric cases, as well as in patients with less emergent (ie, more chronic) hyperkalemic patients, when a slow infusion is desired.

Potassium shifts intracellularly with beta 2-agonists, insulin, saline, and potentially sodium bicarbonate. Insulin is the most reliable agent to move potassium into cells, but beta2-adrenergic receptor agonists also provide benefit in some patients. Insulin, given IV in combination with glucose to prevent hypoglycemia, also shifts potassium into cells by stimulation of the sodium-potassium adenosine triphosphatase (Na\(^{+}\), K\(^{-}\)-ATPase) pump. The onset of action is less than 15 minutes, and the effect is maximal between 30 and 60 minutes, with a maximal drop of 0.6 mEq/L on average.

Nebulized albuterol is effective in shifting potassium into cells by stimulation of the Na\(^{+}\), K\(^{-}\)-ATPase pump. Nebulized albuterol begins to take measurable effect after 15 minutes and lowers the serum potassium level by 0.5 to 1 mEq/L, depending on the dose. The effective dose is at least four times higher than that typically used for bronchodilation. The combination of nebulized albuterol

myocyte excitability and increasing cardiac conduction speed, thus narrowing the QRS. Calcium does not decrease serum potassium levels, and its effect is rapid (within 1 to 3 minutes), but transient (30 to 60 minutes or less). The dose is one ampule, or 10 mL of 10% calcium chloride solution. Calcium chloride is preferably administered through a central venous line due to the risk of tissue necrosis should it extravasate at the injection site. More than 10 mL of calcium gluconate will often be required, because it contains only one-third the calcium contained in calcium chloride. Calcium gluconate is preferred in pediatric cases, as well as in patients with less emergent (ie, more chronic) hyperkalemic patients, when a slow infusion is desired.

Potassium shifts intracellularly with beta 2-agonists, insulin, saline, and potentially sodium bicarbonate. Insulin is the most reliable agent to move potassium into cells, but beta2-adrenergic receptor agonists also provide benefit in some patients. Insulin, given IV in combination with glucose to prevent hypoglycemia, also shifts potassium into cells by stimulation of the sodium-potassium adenosine triphosphatase (Na\(^{+}\), K\(^{-}\)-ATPase) pump. The onset of action is less than 15 minutes, and the effect is maximal between 30 and 60 minutes, with a maximal drop of 0.6 mEq/L on average.

Nebulized albuterol is effective in shifting potassium into cells by stimulation of the Na\(^{+}\), K\(^{-}\)-ATPase pump. Nebulized albuterol begins to take measurable effect after 15 minutes and lowers the serum potassium level by 0.5 to 1 mEq/L, depending on the dose. The effective dose is at least four times higher than that typically used for bronchodilation. The combination of nebulized albuterol

**BOX 117.1**

**Five Most Common Causes of Hyperkalemia**

- Spurious elevation: Hemolysis due to drawing or storing of the laboratory sample or post–blood sampling leak from markedly elevated white blood cells, red blood cells, or platelets
- Renal failure: Acute or chronic
- Acidosis: Diabetic ketoacidosis (DKA), Addison’s disease, adrenal insufficiency, type 4 renal tubular acidosis
- Cell death: Rhabdomyolysis, tumor lysis syndrome, massive hemolysis or transfusion, crush injury, burn
- Drugs: Beta-blockers, acute digitalis overdose, succinylcholine, angiotensin-converting enzyme inhibitors, angiotension receptor blockers, nonsteroidal anti-inflammatory drugs (NSAIDs), spironolactone, amiloride, potassium supplementation

![Fig. 117.1. Hyperkalemia with QRS widening merging into T wave, absent P wave.](image1)

![Fig. 117.2. Hyperkalemia in the same patient as in Figure 117.1 after potassium-lowering therapy has begun. Tall peaked T waves, decreased P wave.](image2)
Control of hyperkalemia in patients with chronic kidney disease and in those with heart failure continues to be difficult. However, two different oral medications, patiromer and sodium zirconium cyclosilicate (ZS-9), have shown clinical promise in ongoing trials to lower serum potassium levels. ZS-9 is a highly selective cation exchanger that entraps potassium in the intestinal tract in exchange for sodium and hydrogen. Patiromer is a non-absorbed polymer that binds potassium in exchanged for calcium, predominantly in the distal colon where the concentration of free potassium is the highest.

and insulin with glucose appears to be additive, lowering serum potassium by a mean of 1.2 mEq/L.

Saline infusions also stimulate the Na\(^+\), K\(^+\)-ATPase pump; only a few hundred milliliters is required for beneficial effects. Saline infusions should be given judiciously in anuric patients and in consultation with a nephrologist. Sodium bicarbonate is effective in hyperkalemic patients who are acidic and has no benefit when used for hyperkalemia in non-acidotic patients. Sodium bicarbonate buffers hydrogen ions extracellularly while shifting potassium intracellularly, but it should be used in combination with other treatment options and reserved for patients with confirmed acidos.

Hemodialysis effectively and reliably decreases serum potassium levels by at least 1 mEq/L in the first hour and another 1 mEq/L during the next 2 hours. It is the only reliable method of potassium removal that has been experimentally studied and should be instituted early in the treatment of life-threatening hyperkalemia in patients with renal failure. In patients with intact renal function, medical management alone is usually sufficient, even in extreme cases, and hemodialysis may not be necessary unless multiple medical modalities fail. There are no randomized trials addressing the use of diuretics (eg, furosemide) in the emergent management of hyperkalemia; but in cases such as rhabdomyolysis or tumor lysis syndrome, it may be appropriate to use a normal saline infusion supplemented by furosemide to enhance diuresis and urinary potassium excretion. Cation exchange resins, such as sodium polystyrene sulfonate (Kayexalate), do not decrease the serum potassium level within the first 4 hours of treatment and is not effective in the acute management of hyperkalemia.

IV: Intravenous.
Hypokalemia is often seen in association with potassium's effect on the heart and muscle, as a level less than 2.5 mEq/L can result in serious cardiovascular instability, neurologic dysfunctions, and endocrine etiologies (Box 117.2). Increased excretion of potassium, especially coupled with poor intake, is the most common cause of hypokalemia, and patients receiving diuretics represent the single most common patient group encountered in clinical practice. Thiazide diuretics are more likely than loop or osmotic diuretics to cause hypokalemia, but both the thiazide and loop diuretics block chloride-associated sodium and increase delivery of sodium to the collecting tubules. Hypokalemia is a common adverse effect of treatment with diuretics and may cause fatal arrhythmias and increase the risk of digitalis toxicity. In addition to diuretics, other drugs and disorders can cause significant renal potassium losses, including hyperaldosteronism, steroid excess, metabolic acidosis, DKA, renal tubular acidosis, and alcohol consumption. When given in large doses, penicillin and its synthetic derivatives promote renal potassium excretion by increasing sodium delivery to the distal nephron. Individuals with secondary hyperaldosteronism, whether due to congestive heart failure (CHF), hepatic insufficiency, or nephrotic syndrome, may also exhibit hypokalemia. Patients with renal tubular acidosis can become hypokalemic, because a defect in the distal tubule leads to increased potassium excretion.

Administration of insulin may cause a reduction in serum potassium because of insulin's ability to stimulate the Na⁺, K⁺-ATPase pump and move potassium intracellularly; hypokalemia can be a dangerous complication with intentional overdoses of insulin or during treatment of DKA. Although most patients with DKA present with high-normal or mildly elevated serum potassium levels, patients are usually 2 to 3 mEq/kg deficient in total body potassium. To avoid hypokalemic arrhythmias or cardiac arrest from hypokalemia, a potassium infusion should be started once significant hyperkalemia has been ruled out and intact renal function confirmed.

Hypokalemia can also occur from gastrointestinal and dermal losses. In diarrhea states, large quantities of potassium can be lost in the stool, with consequent secondary hyperaldosteronism. Large doses of laxatives and repeated enemas also cause excessive potassium loss in the stool. Although hypokalemia is often seen after protracted vomiting or nasogastric suction, only 5 to 10 mEq/L of potassium is lost in gastric fluid. Hypokalemia in this setting is secondary to metabolic alkalosis, chloride losses, and hyperaldosteronism. On occasion, excessive sweating can lead to hypokalemia from potassium losses through the skin. Patients with extensive burns can also suffer from hypokalemia because of significant skin losses. Dietary potassium deficiency should be considered in the severely malnourished patient or chronic alcoholic. Poor potassium intake combined with increased nonrenal losses can result in severe hypokalemia.

Hypokalemia can also result from an acute shift of potassium from the extracellular compartment into cells, most commonly in patients with metabolic alkalosis or hyperventilation, and in patients taking medications such as beta-agonists or decongestants. Stimulation of beta-receptors can lead to hypokalemia, especially in patients using repetitive and high doses of beta-agonists for chronic obstructive pulmonary disease or asthma. A standard dose of nebulized albuterol reduces serum potassium by 0.2 to 0.4 mEq/L, and a second dose taken within 1 hour can reduce it by almost 1 mEq/L. Patients with starvation or near-starvation may develop hypokalemia when fed, as insulin secretion and increased cellular uptake can cause an acute exaggerated intracellular migration of potassium.

**Clinical Features**

Hypokalemia is usually asymptomatic but can present with nonspecific complaints, primarily weakness and muscle pain. Although short periods of mild potassium depletion are typically well tolerated in healthy individuals, severe potassium depletion can result in serious cardiovascular instability, neurologic dysfunction, glucose intolerance, gastrointestinal symptoms, and renal failure, as well as affect the acid-base balance in the body. The likelihood of symptoms appears to correlate with the rapidity of the decrease in serum potassium.

In patients without underlying heart disease, abnormalities in cardiac conduction are extremely unusual, even when the serum potassium concentration is below 3.0 mEq/L. Paresthesias, depressed deep tendon reflexes, fasciculations, muscle weakness,
the risk of torsades de pointes increases twofold to threefold. Hypokalemia is also notorious for causing nonspecific ST and T wave changes. In addition, prolonged potassium depletion of even modest proportion can provoke or exacerbate kidney injury or hypertension. A severe degree of hypokalemia with paralysis is a potentially life-threatening medical emergency and may be seen as levels drop below 2.0 mEq/L.

Management

Because potassium is an intracellular cation; a low serum potassium level almost always reflects a significant total body potassium deficit; each 0.3 mEq potassium drop below normal correlates with an approximately 100 mEq total body deficit. In the absence of nausea or vomiting as the cause of their hypokalemia, patients with mild or moderate hypokalemia may only need oral potassium replacement therapy. Oral replacement is available in liquid, powder, and tablet form. Potassium chloride is the most commonly used supplementation, and 40 to 60 mEq orally every 2 to 4 hours is typically well tolerated. If the cause of hypokalemia is not clear, or the hypokalemia is severe and associated with profound weakness, obtain a spot urine potassium level before starting therapy to assess whether the patient's kidneys are inappropriately wasting potassium from a renal or endocrine cause.

Treatment of hypokalemia is essential in multiple populations of patients. Hypokalemia is arrhythmogenic, especially in the settings of acute myocardial infarction, high catecholamine states, and hypertrophied or dilated ventricles. Hypokalemia is an important independent risk factor for morbidity and mortality in patients with heart failure, requiring serum potassium levels to be maintained above 4.0 and 5.0 mEq/L in this population.

If IV infusion is necessary, potassium chloride can be safely given at a rate of 10 to 20 mEq/hr. In the rare instance when IV repletion is planned at more than 20 mEq/hr, the patient should have continuous cardiac monitoring and central line access established.

Hypokalemia is associated with hypomagnesemia, and the severity of the hypokalemia correlates with a similar degree of hypomagnesemia. Magnesium replacement should usually accompany potassium repletion. Unless the patient receives at least 0.5 g/hr of magnesium sulfate along with potassium replacement, potassium will not move intracellularly and the patient will lose potassium through excretion. Correction of large potassium deficits may require several days, with simultaneous oral and IV replacement.
HYPERNATREMIA

Principles

Hypernatremia is defined as a serum sodium concentration above 145 mEq/ L. It is rarely seen in previously healthy patients and usually portends a poor prognosis. Most hypernatremic patients have either an impaired sense of thirst or no access to water: elders, infants, patients with mental impairment, and those who are intubated and paralyzed are at highest risk for this disorder. Hypernatremia can be divided into three physiologic pairings: (1) hypernatremia with dehydration and low total body sodium, (2) hypernatremia with low total body water and normal total body sodium, and (3) hypernatremia with increased total body sodium (Box 117.3). Diabetes insipidus, an insufficient production of (or lack of response to) antidiuretic hormone, can lead to life-threatening hypernatremia (Box 117.4).

Clinical Features

Patients often have multiple causes of severe hypernatremia. Hypernatremia in adults is almost exclusively due to a free water deficit and should be considered in any patient presenting with altered mental status—individuals with severe mental retardation, cerebral palsy, and head injury, as well as in bed-ridden patients with no access to water. Patients with impaired antidiuretic hormone function may complain of polyuria or polydipsia. Others may have obvious causes of extrarenal fluid losses, while some may have no complaints at all.

**BOX 117.3**

**Three Types of Hypernatremia**

- **HYPERNATREMIA WITH DEHYDRATION AND LOW TOTAL BODY SODIUM**
  - Heatstroke
  - Increased insensible losses: Burns, sweating
  - Gastrointestinal loss: Diarrhea, protracted vomiting, continuous gastrointestinal suction
  - Osmotic diuresis: Glucose, mannitol, enteral feeding

- **HYPERNATREMIA WITH LOW TOTAL BODY WATER AND NORMAL TOTAL BODY SODIUM**
  - Diabetes insipidus
  - Neurogenic
  - Elderly with “reset” osmostat
  - Hypothalamic dysfunction
  - Suprasellar or infrasellar tumors
  - Renal disease
  - Drugs (amphotericin, phenytoin, lithium, aminoglycosides, methoxyflurane)
  - Sickle cell disease

- **HYPERNATREMIA WITH INCREASED TOTAL BODY SODIUM**
  - Salt tablet ingestion
  - Salt water ingestion
  - Saline infusions
  - Saline enemas
  - IV sodium bicarbonate
  - Poorly diluted interval feedings
  - Primary hyperaldosteronism
  - Hemodialysis
  - Cushing’s syndrome
  - Conn’s syndrome

IV, Intravenous.
correction speeds are associated with an increased risk of death, regardless of the initial sodium level. In adult patients who develop hypernatremia over a short time as a result of sodium loading, “rapid correction” at a 1 to 2 mEq/hr decrease in serum sodium appears relatively safe. However, most adult patients develop hypernatremia over days to weeks. In this group of patients, serum sodium concentration should be corrected slowly, at no more than 0.5 mEq/hr or 10 to 12 mEq/day.

Normal saline should be started for volume replacement until the patient is hemodynamically stable, and then changed to half-normal saline at 100 mL/hr once vital signs have normalized. The treatment of central diabetes insipidus with desmopressin (DDAVP) is an effective means of improving polyuria and hypernatremia; initial doses in the acute setting range from 1 to 2 μg.

**HYPONATREMIA**

**Principles**

Hyponatremia, defined as serum sodium concentration of less than 135 mEq/L, is the second most common electrolyte abnormality encountered in clinical practice and can be a marker of underlying disease. The most common cause of severe hyponatremia in adults are therapy with thiazides, the postoperative state the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), psychogenic polydipsia, exercise-associated hyponatremia, and unintentional water intoxication. Gastrointestinal fluid loss, ingestion of overly dilute formula, accidental ingestion of excessive water, and receipt of multiple tap water enemas are the main causes of severe hyponatremia in infants and children. Most patients presenting to the emergency department (ED) with hyponatremia are asymptomatic and do not require emergent therapy. If symptoms are present, they are typically based on the degree of hyponatremia and how acutely the hyponatremia developed. Symptoms range from headache, nausea, and vomiting to confusion, seizures, and coma. There are two groups of hypotonic patients that will require treatment with either normal saline or hypertonic saline: (1) severe but asymptomatic hyponatremia with a sodium level below 110 mEq/L or less and (2) acute symptomatic hyponatremia with a sodium level below 120 mEq/L.

Central nervous system (CNS) damage due to hyponatremia may be caused by cerebral edema and increased intracranial pressure, by osmotic fluid shifts during overly aggressive treatment, or by both. When neurons are subjected to a hyponatremic environment, they become depleted of sodium and potassium in an attempt to limit their own osmolarity to prevent intracellular fluid shifts that would lead to cerebral edema. If fluid therapy raises extracellular sodium levels too quickly, fluids shift out of neurons and can cause diffuse demyelination. This can result in a flaccid paralysis and death due to central pontine myelinolysis, a syndrome more accurately labeled as the osmotic demyelinating syndrome (ODS).

Causes of hyponatremia fall into four general categories: pseudohyponatremia, hyponatremia with dehydration and decreased extracellular volume, hyponatremia with increased extracellular volume, and euvoletic hyponatremia with increased TBW (Box 117.5).

**Pseudohyponatremia**

Pseudohyponatremia is a falsely low sodium reading caused by the presence of other osmolar particles in the serum. The phenomenon of pseudohyponatremia is explained by the increased percentage of large molecular particles that do not contribute to plasma osmolality relative to sodium. Severe hypertriglyceridemia and hyperproteinemia are two common causes of this condition. Blood draw or laboratory error should also be considered as a possible cause of hyponatremia, especially if the blood sample was drawn near an infusion site using 5% dextrose in water (D5W) when a very abnormal sodium level is reported in an otherwise healthy patient.

Hyperglycemia is sometimes considered a cause of pseudohyponatremia; however, it actually causes a dilutional hyponatremia by pulling water into the vascular space through osmosis. In true pseudohyponatremia, serum osmolality is normal and no shifts of water occur. Two different formulas based on the degree of a patient’s hyperglycemia are currently used to correct serum sodium levels. The most commonly recommended formula advocates for the addition of 1.6 mEq/L to the measured sodium for every 100 mg/dL of glucose above 100. However, another acceptable formula recommends use of 2.4 mEq as the correction factor because glucose values above 400 mg/dL may lower sodium values by 4 mEq/L per each 100 mg/dL of glucose rise. Either formula is acceptable to use, the key concept being that as glucose levels rise significantly, a “normal” serum sodium is distinctly abnormal.

**Hypovolemic Hyponatremia**

Hypovolemic hyponatremia, or hyponatremia with dehydration, occurs when there is decreased extracellular volume combined with an even greater loss of sodium. Hyponatremia secondary to
Renal Volume

Renal Edematous

Normal

Extrarenal

CHF, hormone secretion. For similar reasons, there are extensive case reports of significant exercise-associated hyponatremia in endurance athletes. SIADH is an important cause of hyponatremia that occurs when antidiuretic hormone is secreted independent of the body's need to conserve water. The process results from excess antidiuretic hormone production that increases TBW, causing the serum sodium to decrease. Patients with SIADH inappropriately concentrate their urine, despite a low serum osmolality and normal circulating blood volume. Despite excess TBW, they have no signs of edema, ascites, or heart failure, because most of the increased water is intracellular rather than intravascular. The three most common causes of SIADH are (1) pulmonary lung masses and infections, (2) CNS disorders, and (3) drugs (Box 117.6). Lung cancers (especially small cell cancer), pneumonia, and tuberculosis can lead to SIADH. CNS infections, masses, and psychosis can also cause SIADH. A large number of medications are associated with SIADH, the most common of which are thiazide diuretics, narcotics, lithium, oral hypoglycemics, barbiturates, and antineoplastics. The mainstay of treatment of most patients with SIADH and other causes of euvolemic hyponatremia is free water restriction.

Diagnostic Testing

A spot urinary sodium or urinary chloride level can help determine if hyponatremia is renal in origin (Table 117.3). Patients with hypovolemic hyponatremia due to nonrenal causes typically have a low urinary sodium or chloride level (<20 mEq/L), because they try to retain solute. Patients with hypervolemic hyponatremia due to renal causes will have elevated urine sodium and chloride levels (>20 mEq/L), because their kidneys cannot retain sodium or chloride. Patients with euvolemic hyponatremia typically have a urinary sodium concentration more than 20 mEq/L secondary to volume expansion caused by water retention. Patients with psychogenic polydipsia who are ingesting large quantities of water will try to diurese and have dilute urine with low quantities of urinary sodium. Patients with hypervolemic hyponatremia secondary to CHF or cirrhosis have urine sodium levels of less than 20 mEq/L because of renal hypoperfusion, whereas those with

**Hypovolemic Hyponatremia**

Hypovolemic hyponatremia, or hyponatremia with increased extracellular volume, occurs when sodium and water are retained, but water retention exceeds sodium retention. Most of these patients present with edema. Hyponatremia with increased total body sodium occurs in patients with heart failure, chronic renal failure, and hepatic failure. The fluid retention in these states is secondary to renal hypoperfusion, resulting in increased aldosterone secretion and a decrease in free water excretion.

**Euvolemic Hyponatremia**

The final category of hyponatremia is one in which patients are euvoletic but have increased TBW. Causes of this type of hyponatremia include SIADH, psychogenic polydipsia beer potomania, hypothyroidism, diuretic use in patients with mild CHF, and accidental or intentional water intoxication. Euvolemic hyponatremia has also been described in patients after the use of the recreational drug N-methyl-3,4-methylenedioxyamphetamine (MDMA; or ecstasy). MDMA-induced hyponatremia is multifactorial and related to increased free water intake to avoid dehydration and rhabdomyolysis, along with the tendency to be very active while using the drug, leading to sweating and antidiuretic hormone secretion. For similar reasons, there are extensive case reports of significant exercise-associated hyponatremia in endurance athletes.

CHF, Congestive heart failure; SIADH, syndrome of inappropriate antidiuretic hormone secretion.
renal causes of hypervolemic hyponatremia or with SIADH have sodium levels more than 20 mEq/L, because their kidneys do not retain sodium. In interpreting serum sodium levels, consider the possibility of sampling error if the reported value does not seem consistent with the patient’s presentation and confirm that a diuretic such as furosemide, which will increase urinary sodium losses, has not been recently administered. Consider adrenal insufficiency when a dehydrated patient has both hyponatremia and hyperkalemia.

Clinical Features

The signs and symptoms of hyponatremia worsen as sodium levels decline and also correlate with how rapid hyponatremia develops. Nonspecific signs of hyponatremia include anorexia, nausea, vomiting, and generalized weakness. Acutely hyponatremic patients whose sodium level drops below 120 mEq/L over 24 to 48 hours may present with severe neurologic findings, including confusion, seizures, coma, and brainstem herniation. Determination of the hydration status of the patient may help establish the etiology of the hyponatremia and direct subsequent treatment. Hypovolemic hyponatremia is more likely in the patient with diminished skin turgor, increased capillary refill, dry mucous membranes, and orthostasis, while the patient with jugular venous distention, peripheral edema, or pulmonary congestion is much more likely to have hypervolemic hyponatremia. Patients with SIADH will have no edema and normal skin turgor. Of note, in geriatric patients, the risk of hyponatremia doubles for those presenting with large-bone fractures.

Management

Treatment of hyponatremia is guided by the patient’s clinical presentation, severity of symptoms, estimated duration of illness, fluid status, and underlying cause of the sodium disturbance. Typically, sodium should be corrected during a time course of 48 to 72 hours. The neurologic changes, including flaccid paralysis, dysarthria, dysphagia, and hypotension, associated with overly rapid sodium correction are referred to as osmotic demyelinating syndrome (ODS), previously termed central pontine myelinolysis. Most ODS cases occur in the alcoholic, malnourished, and elder population, although this devastating side effect can occur in young healthy patients as well. If a patient develops symptoms of ODS during therapy, all sodium-containing fluids should be stopped and D5W administered immediately to temporarily lower sodium values. Most patients presenting to the ED with hyponatremia are stable and require no emergent therapy. However, patients who have serum sodium levels of significantly less than 120 mEq/L and those who have acute alterations in mental status, seizures, or new focal findings due to hyponatremia need immediate intervention. Table 117.4 presents the sodium concentration of various infusates, and the following equation is helpful to estimate the effect of 1 liter of any infusate on serum sodium:

\[
\text{Change in serum } Na^+ = \text{infusate } Na^+ - \text{serum } Na^+ / \text{TBW} + 1
\]

There is no consensus regarding the optimal treatment of symptomatic hyponatremia. However, there is agreement that correction should occur at a sufficient pace and magnitude to reverse the manifestations of hypotonicity but not be so rapid as to pose a risk for development of ODS. For relatively asymptomatic patients with sodium values of 115 to 135 mEq/L, free water restriction is typically the single most important treatment. In more severe cases when the sodium value is 120 mEq/L or less and the patient has alterations in mental status, has focal findings, or is seizing, 3% hypertonic saline (513 mEq/L of sodium) is indicated. Correction of hyponatremia by 4 to 6 mEq/L within 6 hours, with bolus infusions of 3% saline if necessary, is sufficient to manage the most severe manifestations of hyponatremia. Initially, 100 mL of 3% hypertonic saline should be infused over 10 minutes. If a second bolus is required, an additional 100 mL of the 3% solution may be administered during the next 50 minutes. To minimize the likelihood of ODS, it is essential that symptomatic patients with severe hyponatremia have serum sodium levels raised slowly. Previous guidelines have endorsed the safety of raising the serum sodium by up to 10 to 12 mEq within the first 24 hours. However, in patients believed to have been hyponatremic for more than 48 hours, severe hyponatremia should be corrected by no more than 8 mEq in the first 24 hours.

Potassium deficits should be replaced aggressively in the treatment of hyponatremic patients with a sodium disorder. If patients are retaining volume and diuresis is not adequate, furosemide can be used; D5W is infused if the sodium level is rising too quickly. Patients may be able to make full neurologic recoveries from ODS with the reinduction of hyponatremia in these extreme cases. Demeclocycline in a dosage of 600 to 1200 mg daily is effective in patients with refractory hyponatremia.

Hypervolemic Hyponatremia

Treatment of hypervolemic hyponatremia begins with rehydration. Hypotensive, dehydrated patients should be volume resuscitated with normal saline. Once the patient is hemodynamically stable, the infusion rate should be slowed. Typically, normal saline is started at 500 to 1000 mL/hr until the blood pressure is stable and then slowed to 200 mL/hr with frequent sodium checks. If the sodium value is below 120 mEq/L, the sodium concentration should be allowed to rise only by an average of 0.5 mEq/hr or 10 to 12 mEq/day. The underlying cause of hyponatremia should be identified and treated.

Hypervolemic Hyponatremia

Normal saline and hypertonic saline can cause pulmonary edema in the hypervolemic hyponatremic patient. Restriction of fluid and sodium is the preferred treatment, although loop diuretics can be used in severe cases. Hemodialysis is an alternative in patients with renal impairment and should be considered for significantly hyponatremic renal failure patients with volume overload. Patients with CHF will usually benefit from diuretics that will increase water excretion and cause vasodilation to improve cardiac output. In patients with liver failure, albumin is a consideration, along with diuretics and possibly paracentesis to improve the underlying pathologic process. Water restriction

may make the largest impact on the long-term care of these patients.

**Euvolemic Hyponatremia**

The mainstay of treatment of euvoletic hyponatremia is free water restriction, as hypo-osmolality in SIADH results from a relative abundance of water in the intracellular and extracellular spaces, maintained by a reduced ability to excrete water. However, water restriction is insufficient to treat acute severe hyponatremia and is not recommended as a sole intervention for patients requiring more rapid correction based on clinical presentation. The only definitive treatment of SIADH is elimination of its underlying cause. Most cases of SIADH caused by malignant disease resolve with effective antineoplastic therapy; most due to medication resolve promptly when the offending agent is discontinued.

In patients with SIADH, normal saline may cause the serum sodium concentration to fall even more as free water is retained and hypertonic urine is excreted. If a patient is symptomatic because of a rapid decrease in serum sodium concentration, treatment with hypertonic saline is recommended. Rapid correction of hyponatremia may occur during hemodialysis. To minimize the risks of ODS, hemodialysis is reserved for patients with documented renal failure under close monitoring. Vaptans, which are oral agents that inhibit the effects of vasopressin, have been studied for treatment of patients with hyponatremia due to SIADH but need further evaluation before becoming standard of care.18,22

**HYPERCALCEMIA**

**Principles**

Hypercalcemia is usually defined as a serum calcium level above 10.5 mg/dL; normal levels are usually defined as between 9 and 10.5 mg/dL. Hypercalcemia is considered mild if the total serum calcium level is between 10.5 and 12 mg/dL; levels higher than 14 mg/dL can be life-threatening. Hypercalcemic crisis typically evolves from preexisting mild hypercalcemia, which develops into an acute severe hypercalcemic emergency.

There are five major causes of hypercalcemia (Box 117.7). Hyperparathyroidism is the most common cause of hypercalcemia in outpatients, whereas malignancy is the most common cause in hospitalized patients; together, these two etiologies account for 80% of hypercalcemia cases.21b Mild hypercalcemia, in an otherwise normal person, may be due to thiazide diuretics in the setting of minimal dehydration. Other less common causes of elevated calcium concentration should be considered after malignant disease and parathyroid disease are ruled out. Malignancy-associated hypercalcemia occurs in up to 10% of all patients with advanced cancer and generally conveys a poor prognosis. Other causes of hypercalcemia include granulomatous disease, such as sarcoidosis and tuberculosis; medications and pharmacologic agents; and a number of diverse conditions, such as rhabdomyolysis and prolonged immobilization.

**Clinical Features**

The clinical presentation of hypercalcemia is often vague and nonspecific. Symptoms include nonfocal abdominal pain, constipation, fatigue, body aches, anorexia, polydipsia, polyuria, nausea, and vomiting. Symptom severity depends on the degree of hypercalcemia, the rapidity of onset, and the patient's baseline neurologic and renal function. Neuropsychiatric disturbances include anxiety, depression, and hallucinations. The CNS manifestations that often predominate in more severe cases include lethargy, altered mental status, seizures, and coma. Death due to hypercalcemia is usually related to complications caused by coma, dehydration, or electrolyte disturbances. Cardiac conduction abnormalities may occur; bradydysrhythmias are the most common. Severe hypercalcemia (>14 mg/dL) has also been associated with sinus arrest, atrioventricular block, atrial fibrillation, and ventricular tachycardia.

**Diagnostic Testing**

The diagnostic evaluation of a patient with suspected hypercalcemia begins with obtaining of electrolyte and renal function tests and an ECG. Calcium is measured by determination of either a total serum calcium level or an ionized calcium level. Ionized calcium is the active form of the total calcium level. Ionized calcium is more accurate in the diagnosis and treatment of hypercalcemia but does need to be routinely evaluated in hypercalcemia. The serum total calcium level represents both bound and unbound calcium and, thus, should be corrected on the basis of the albumin concentration. The adjustment to serum albumin is accomplished by adding or subtracting 0.08 mg/dL to the measured total serum calcium for every 1.0 g/L of albumin below or above 4 g/L albumin, respectively.

A short QT interval can be seen in hypercalcemia and is considered a classic finding. However, although the incidence and duration of QT shortening appear to be correlated with the degree of hypercalcemia, it is not a reliable finding and is not routinely seen in most patients (Fig. 117.6). ST segment elevation may be the least well documented but most consistent electrocardiographic finding, making hypercalcemia a potential cause of ST segment elevation caused by conditions other than myocardial infarction.21 In severe cases of hypercalcemia, sinus bradycardia, bundle branch block, and high-degree atrioventricular block may also be seen.

**Management**

Patients in hypercalcemic crisis are usually dehydrated, often obtunded, and also predisposed to arrhythmias as a result of concomitant electrolyte disturbances; thus, they require IV access with a normal saline infusion and close monitoring. Normal saline will inhibit proximal tubule reabsorption of calcium and correct the patient’s volume depletion. Normal saline should be infused “wide open” until blood pressure and perfusion are

**MISCELLANEOUS**

Dehydration, prolonged immobilization, iatrogenic, rhabdomyolysis, familial, laboratory error
normalized. After the initial bolus, the saline infusion should be adjusted to a rate of approximately 200 to 300 mL/hr (depending on the patient’s age, renal function, cardiac and other comorbid diseases) to establish adequate urine output (2 L/day). Although the administration of higher volumes of saline may further augment calcium excretion, it is much more likely to result in increased morbidity and mortality from volume overload, pulmonary edema, and myocardial ischemia. The routine use of furosemide in the management of hypercalcemia is no longer recommended. Furosemide was once thought to block the distal reabsorption of calcium, thus complementing saline’s proximal tubule effects. However, furosemide has not been shown to have significant calcium reabsorption blocking effects. The use of furosemide should be reserved for augmenting saline diuresis to avoid volume overload during the treatment of hypercalcemia. If a loop diuretic is given to patients who are not yet volume replete, not only can the patient’s hemodynamics and renal status deteriorate, but hypercalcemia may worsen. Once calcium excretion by saline infusion has begun, other electrolyte values should be carefully monitored, with particular attention to serum potassium levels.

Osteoclast-inhibiting therapies for severe hypercalcemia are generally considered in consultation with the patient’s primary physician or oncologist. Drugs that inhibit osteoclast-mediated bone resorption include the bisphosphonates, mithramycin, calcitonin, and glucocorticoids. IV bisphosphonates are the most extensively studied and most efficacious agents for the treatment of malignancy-associated hypercalcemia. Their calcium-lowering effect is achieved predominantly by inhibition of osteoclast function and survival. Zoledronic acid is the bisphosphonate of choice in hypercalcemia of malignancy. The infusion takes 15 minutes; zoledronic acid may be more effective than other bisphosphonates at keeping the calcium level down over time. The use of IV bisphosphonates is restricted to the treatment of acute hypercalcemia associated with serum calcium concentrations above 15 mg/dL and rapid deterioration of CNS, cardiac, gastrointestinal, and renal function.

In the rare case in which a patient has a life-threatening hypercalcemic arrhythmia or heart block, phosphates and hemodialysis should be considered. In cases of hypercalcemic crisis resulting from primary hyperparathyroidism, urgent parathyroidectomy is potentially curative. Isolated mild hypercalcemia rarely requires urgent treatment; however, an outpatient hypercalcemia evaluation should be discussed in patients’ discharge plans, because up to 20% will ultimately be diagnosed with hyperparathyroidism.

**HYPOCALCEMIA**

**Principles**

Calcium regulation is critical for normal cell function, neural transmission, membrane stability, bone structure, blood coagulation, and intracellular signaling. Total body calcium is controlled by a feedback system in which parathyroid hormone induces the bone and the kidneys to increase serum calcium levels. Vitamin D facilitates intestinal calcium absorption. Conversely, elevated calcium levels normally inhibit parathyroid hormone release.

There are multiple causes of hypocalcemia, of which hypobalbuminemia is the most common. Because calcium is bound to albumin and other serum proteins, hypobalbuminemia will cause a fall in the measured serum calcium by about 0.8 mg/dL for every 1 g/dL reduction in serum albumin. The active form of calcium is the ionized calcium, which is not affected by changes in albumin.

---

**BOX 117.8**

**Most Common Causes of Hypocalcemia**

- Hypoalbuminemia
- Hypoparathyroidism: inherited, postsurgical, autoimmune, infiltrative
- Vitamin D deficiency and vitamin D resistance: Malabsorption syndrome, liver disease, malnutrition, sepsis, anticonvulsants, lack of sunlight exposure
- Chronic renal failure
- Hyperphosphatemia
- Hypomagnesemia
- Respiratory alkalosis
- Severe pancreatitis
- Drugs: Bisphosphonates, phenytoin, phosphate, calcitonin
- Tumor lysis syndrome
- Rhabdomyolysis

---
Hypoparathyroidism is a common cause of hypocalcemia and often develops after surgery for head and neck cancers; it develops in 1% to 2% of patients after total thyroidectomy. Patients with vitamin D deficiency, including those with malabsorption syndromes, liver disease, malnutrition, and very little sunlight exposure, are at high risk for development of hypocalcemia. Derangements in magnesium and phosphate can also lead to hypocalcemia. Hyperphosphatemic patients often have hypocalcemia because of phosphate's affinity to bind calcium, whereas hypomagnesemia causes end-organ resistance to parathyroid hormone and inhibits the hypocalcemic feedback loop. Patients with sepsis demonstrate hypocalcemia usually associated with hypoalbuminemia.

The most common causes of symptomatic hypocalcemia are massive blood transfusions, toxins, pancreatitis, tumor lysis syndrome, and chronic malnutrition (Box 117.9). Patients receiving massive blood transfusions are at risk for development of hypocalcemia because of citrate toxicity. Rapid blood transfusions and radiocontrast dyes containing citrate infusions should be monitored closely in patients with hepatic failure, CHF, or other low-output states to avoid hypocalcemia.

Hypocalcemia in acute pancreatitis is caused primarily by precipitation of calcium soaps in the abdominal cavity, but glucagon-stimulated calcitonin release and decreased parathyroid hormone secretion may play a role. Toxic exposures to hydrofluoric acid and ethylene glycol can cause profound hypocalcemia secondary to their abilities to complex and chelate with calcium. Patients being treated for malignant neoplasms are at risk for development of tumor lysis syndrome and multiple secondary electrolyte abnormalities. Hypocalcemia has been attributed to the precipitation of calcium phosphate salts. Finally, one should expect to encounter hypocalcemia in malnourished patients and chronic alcoholics who present to the ED, especially alcoholics with hyperventilation due to alcohol withdrawal.

Clinical Features

Although there are many clinical manifestations of hypocalcemia, neuromuscular and cardiovascular findings predominate. Severity of symptoms is related to not only the absolute calcium level, but also the rate calcium rise. The patient may complain of muscle cramping, perioral or finger paresthesias, shortness of breath secondary to bronchospasm, and tetanic contractions. Symptomatic hypocalcemia may result in cardiovascular collapse, hypotension, and dysrhythmias. More severe hypocalcemia can lead to cardiovascular collapse, hypotension, syncope, dysrhythmias, CHF, angina, hypotension, and QT prolongation.25a Chronic hypocalcemia may manifest with cataracts, poor dentition, dry skin, coarse hair, and pruritus. Chvostek’s sign may be present: when the examiner taps the facial nerve, facial or eye muscle twitching will be elicited. Trousseau’s sign may also be present; when the examiner inflates the blood pressure cuff to 20 mm Hg above the systolic blood pressure for 3 minutes, carpal spasms will be induced because of the increased excitability caused by local ulnar and median nerve ischemia. Trousseau’s sign is relatively specific for hypocalcemia, whereas Chvostek’s test is less diagnostic.

Diagnostic Strategies

Most cases of hypocalcemia are discovered by clinical suspicion followed by appropriate laboratory testing. A serum calcium level less than 8.5 mg/dL or an ionized calcium level less than 2.0 mEq/L is considered diagnostic. Total serum calcium is approximately 50% free (ionized) and 50% bound, primarily to albumin; thus the serum level should be “corrected” when hypoalbuminemia exists. The ionized calcium level, which is not affected by the albumin level, is more accurate. It is best to perform the whole blood ionized calcium determination rapidly to avoid changes in chelation and pH. In select cases, a parathyroid hormone level may be sent to assist the admitting or consulting physician. Electrocardiography and cardiac monitoring are recommended in suspected hypocalcemia patients to evaluate the QT interval and to provide continuous monitoring for potential dysrhythmias.

Management

Most asymptomatic patients and those with mild symptoms can be treated with oral calcium supplementation, such as calcium carbonate. IV calcium is administered, either as calcium chloride or calcium gluconate, to patients with moderate to severe symptoms; 100 to 300 mg of elemental calcium given over 5 to 30 minutes will raise the ionized calcium level 0.5 to 1.5 mEq. Calcium chloride contains 272 mg of elemental calcium but can be caustic to veins, so it should be given via central venous access unless patients are critically ill without central access. Calcium gluconate contains 92 mg of elemental calcium. Although this is one-third the amount contained in calcium chloride, it is safer to administer and can be given peripherally. Most patients requiring IV calcium should be admitted to the hospital for monitoring and treatment of nausea, vomiting, hypertension, and bradycardia. Patients taking digoxin have increased cardiac sensitivity to fluctuations in serum calcium, so IV calcium administration should be accompanied by continuous electrocardiographic monitoring.20

HYPERMAGNESEMIA

Principles

Hypermagnesemia is a relatively rare electrolyte abnormality defined as a serum magnesium concentration above 2.2 mg/dL. Hypermagnesemia is most often seen in patients who cannot optimally regulate magnesium excretion (eg, renal insufficiency), especially as their magnesium load increases. There have been reports of fatal and near-fatal cases involving hypermagnesemia in patients receiving magnesium with unrecognized renal failure. Hypermagnesemia can also be caused by over-the-counter laxatives and antacids. Even though most patients at risk for hypermagnesemia have underlying renal impairment, hypermagnesemia has been reported in patients with normal renal function, especially in elders. Box 117.10 lists the most common causes of increased serum magnesium levels.

Iatrogenic hypermagnesemia most commonly occurs from excessive IV infusions of magnesium in patients being treated for preeclampsia or eclampsia, cardiac arrhythmias, or asthma exacerbations. Magnesium administration during eclampsia can also cause fetal hypermagnesemia as magnesium crosses the placental membrane.
BOX 117.10

Five Most Common Causes of Hypermagnesemia

- Iatrogenic: IV administration, dialysate
- Oral administration: Laxatives, antacids, vitamins, cathartics, dialysate, parental
- Impaired elimination—hypomotility: Bowel obstruction, chronic constipation
- Impaired elimination—medications: Anticholinergics, narcotics, lithium therapy
- Miscellaneous: Hypothyroidism, tumor lysis syndrome, adrenal insufficiency, milk-alkali syndrome

Diagnostic Testing

Measured plasma magnesium levels often do not reflect total magnesium content, making it difficult to consistently correlate symptoms to specific magnesium levels. Although there is some question of the role of measuring ionized magnesium in patients with hypomagnesemia, only total body magnesium needs to be followed in hypomagnesemic patients.

Management

Management of hypermagnesemia is dictated by the neuromuscular, cardiovascular, and CNS changes that occur. Most stable or asymptomatic hypermagnesemic patients can be treated with cessation of their magnesium therapy. As symptoms become more pronounced, IV isotonic fluids are administered to dilute the extracellular magnesium. Diuretics can be used to promote excretion of magnesium while more definitive treatment is arranged.

In patients with higher levels of serum magnesium or more severe symptoms, renal consultation should be initiated immediately to arrange for dialysis. IV calcium therapy to reverse magnesium toxicity should be reserved for patients with life-threatening symptoms while dialysis is being arranged. Calcium directly antagonizes the neuromuscular and cardiovascular effects of magnesium and is recommended in hypotensive patients with respiratory depression and cardiac instability. In treating life-threatening hypermagnesemia, initially administer 100 to 200 mg of IV calcium as either calcium chloride or calcium gluconate (1 to 2 mL of 10% calcium chloride or 5 mL of 1% calcium gluconate over 2 to 5 minutes) and then titrate to effect. When needed, a continuous infusion at 2 to 4 mg/kg/hr can be administered while dialysis is being arranged.

HYPOMAGNESEMIA

Principles

Hypomagnesemia is a common electrolyte abnormality that often goes undetected. Normal serum magnesium levels range from 1.5 to 3.0 mEq/L. Symptoms of hypomagnesemia typically begin to be manifested at serum levels below 1.2 mEq/L, although symptoms are often not well correlated with the patient’s serum level. This is because most of the body’s magnesium is intracellular, and thus a single blood sample with a low serum magnesium level may not accurately reflect total body magnesium or the extent of true hypomagnesemia.

Magnesium exists in three states: (1) ionized magnesium, (2) protein bound, and (3) complexed to serum anions. Even though studies show the importance of measuring ionized calcium, most research shows that ionized magnesium can be inferred from total magnesium. Currently, the clinical role of measurement of ionized magnesium is unclear, and measurement of ionized magnesium is not standard practice in the ED; there may be a role for measurement of ionized magnesium in the intensive care setting.

There are many causes of hypomagnesemia (Box 117.11). The following sections describe the five most common ED presentations of hypomagnesemia.
Patients Maintained on Diuretics

Patients using either loop or thiazide diuretics are at increased risk for hypomagnesemia. Both types of diuretics can inhibit magnesium reabsorption. Conversely, potassium-sparing diuretics are also magnesium sparing, because they enhance magnesium reabsorption and decrease magnesium excretion. The degree of hypomagnesemia induced by the loop and thiazide diuretics is generally mild, in part because the associated volume contraction will tend to increase proximal sodium, water, and magnesium reabsorption.

Malnourished and Alcoholic Patients

Healthy patients consume enough magnesium in green vegetables, legumes, fruits, shellfish, fresh meat, and cocoa on a regular basis to maintain normal total body magnesium stores. However, hypomagnesemia is common in patients with chronic protein-calorie malnutrition because of an associated lack of essential minerals and vitamins including magnesium. This is especially true in chronic alcoholics who may not eat foods rich in magnesium. Magnesium losses are further increased in chronic alcoholics because of alcohol’s diuretic effects. Hypomagnesemia may also be seen in patients with malabsorption disorders (celiac sprue and short bowel syndrome), patients with increased magnesium excretion (chronic diarrhea or inflammatory bowel conditions), and patients with severe body dysmorphic disorders. Mild hypokalemia is common following CPR, but severe hypokalemia below 2.5 mmol/L after resuscitation should prompt concern about underlying eating disorders and further evaluation due to extreme accidental self-induced hypokalemia.

Patients With Hypokalemia

Both potassium and magnesium are critical to help stabilize the membrane potential, to decrease cell excitability, and for function of the Na+, K+-ATPase pump. Approximately 50% of patients with hypokalemia also have concomitant magnesium deficiency. Increasing degrees of hypokalemia are correlated with an increasing likelihood of a magnesium deficit. Hypokalemic patients who are refractory to potassium replacement are likely to also be hypomagnesemic.124

Patients With Acute Coronary Artery Disease and Ventricular Arrhythmias

There appears to be a relationship between low serum magnesium levels and the subsequent development of coronary heart disease. Patients who have a myocardial infarction are more likely than controls to be hypomagnesemic.28a At present, magnesium supplementation is recommended only for those acute coronary syndrome patients who have evidence of hypokalemia, prolonged QT, or known hypomagnesemia. Similarly, patients with acute myocardial infarction who have mild hypomagnesemia appear to have a twofold to threefold increase in the frequency of ventricular arrhythmias in the first 24 hours compared with those with normal magnesium levels. There is controversy about whether magnesium should be administered empirically after acute myocardial infarction.27 Dysrhythmia is the most common cardiovascular manifestation of hypomagnesemia. Magnesium affects the duration of phase 2 of the action potential, and hypomagnesemia can prolong the QT interval. Magnesium also has effects on phase 4, the resting membrane potential, where it keeps the cell more negative by stimulating the sodium-potassium pump. The exact mechanism underlying a possible association between hypomagnesemia and arrhythmias is unknown. Arrhythmias are likely to be due to concurrent hypokalemia, hypomagnesemia, or both, resulting in a prolonged QT interval and increases in spontaneous depolarization.

Patients Receiving Specific Medications

In addition to diuretics, many medications are associated with hypomagnesemia. Many nephrotoxic drugs, including aminoglycosides, amphotericin B, cisplatin, and pentamidine, can produce magnesium wasting. Long-term use of proton pump inhibitors may be associated with changes in intestinal absorption of magnesium.30 Severe hypomagnesemia can also be seen in patients preparing for colonoscopy with polyethylene glycol–based bowel preparations.

Clinical Features

Determination of the clinical consequences of isolated hypomagnesemia is often confounded by coexisting hypokalemia, hypocalcemia, or hyponatremia. However, many signs and symptoms are reported to correlate with hypomagnesemia, including muscle cramping, diffuse weakness, palpitations, vertigo, ataxia, depression, and seizures. Women with an adequate intake of magnesium are less likely to be affected by preeclampsia. The clinical manifestations most likely seen in the ED involve the neuromuscular and cardiovascular systems. Patients may present with hyperactive deep tendon reflexes, muscle cramps, Trousseau’s and Chvostek’s signs, and dysarthria and dysphagia from esophageal dysmotility.31a Cardiac conduction abnormalities secondary to magnesium depletion, and often coexisting hypokalemia, can result in PR, as well as QT interval prolongation. Dysrhythmias including atrial fibrillation, multifocal atrial tachycardia, premature ventricular complexes, ventricular tachycardia, torsades de pointes, and ventricular fibrillation are the most common cardiovascular manifestations of hypomagnesemia. Severe hypomagnesemia can also precipitate digoxin-induced dysrhythmias.31b

Diagnostic Testing

Clinical manifestations of hypomagnesemia begin at serum levels below 1.2 mEq/L, but symptoms do not always correlate with the total serum magnesium level. Because most of the total body magnesium is intracellular, the magnesium level alone does not guide therapy. However, the possibility of hypomagnesemia is considered in patients with malnourishment, significant or refractory hypokalemia, and ventricular arrhythmias. Electrocardiographic findings in hypomagnesemia are nonspecific and may be caused by both the hypomagnesemia and concomitant hypokalemia. Hypomagnesemia should be suspected whenever electrocardiographic findings of hypokalemia are noted, including PR and QT interval prolongation, ST segment depression, flattening and widening of the T waves, loss of voltage, and U waves.

Management

The route of magnesium repletion varies with the severity of the clinical manifestations. Parenteral magnesium is recommended
for life-threatening conditions. In patients with normal renal function, 1 to 2 g of magnesium sulfate is an appropriate loading dose. A stable patient with hypomagnesemia can be treated with a loading dose of 1 to 2 g of magnesium sulfate during 10 to 60 minutes, followed by a maintenance dose of 0.5 to 1 g/hr until symptoms have resolved. However, patients in cardiac arrest should receive a bolus of 1 to 2 g magnesium sulfate by IV push.

Magnesium administration is strongly encouraged for patients receiving IV potassium repletion. A dose of 0.5 g/hr is safe in patients who are well hydrated and have normal renal function. There are potential adverse effects to rapid magnesium replacement at more than 1 to 2 g/hr, including decreased deep tendon reflexes, respiratory depression, and heart block. Magnesium gluconate oral supplementation can be given if the patient is only mildly hypomagnesemic and asymptomatic. Oral absorption is variable, but most commonly magnesium oxide 400 mg twice daily can be administered to patients with adequate renal function. When preparing any patient for discharge, physicians can encourage lifestyle changes, including adequate magnesium intake that may benefit blood pressure control, promote weight loss, and improve chronic disease risk.

HYPERPHOSPHATEMIA

Principles

Hyperphosphatemia is defined as a serum level above 2.5 mg/dL, but it is usually clinically significant only when levels are greater than 5 mg/dL. Although it is rare in the general population, hyperphosphatemia is extremely common in patients with renal insufficiency or renal failure. Almost all patients with renal failure experience hyperphosphatemia at some time during the course of their disease. Hyperphosphatemia can occur because of four major pathways: (1) decreased phosphate excretion, (2) excessive phosphate intake, (3) increased renal tubular reabsorption, and (4) shift of phosphate from intracellular to extracellular space. In addition, physicians should be aware of spurious elevations in phosphate (Box 117.12).

Decreased excretion of phosphate combined with excessive intake is the most common mechanism for the development of hyperphosphatemia. Excessive phosphate intake alone is an uncommon cause of hyperphosphatemia in patients with normal renal function. When patients have glomerular filtration rates below 30 mL/min, the kidneys do not excrete the full amount of ingested phosphate to maintain homeostasis. Exogenous phosphate, including IV or oral phosphate administration and phosphate enemas and laxatives can cause a large burden on the kidneys if they do not have normal baseline function. In 2014, the U.S. Food and Drug Administration (FDA) made a drug safety announcement after identifying over 50 cases of adverse events warning against utilizing a single dose of sodium phosphate larger than recommended or taking more than one dose in a day, especially in patients also taking medications that act on renal function. Hyperparathyroidism, vitamin D intoxication, and thyrotoxicosis increase renal phosphate reabsorption and may cause elevated phosphate levels. Hyperphosphatemia may also occur when there is a large shift of phosphate from the intracellular to the extracellular space and the kidney’s ability to excrete phosphate is overwhelmed. This cause of hyperphosphatemia is seen in rhabdomyolysis, tumor lysis syndrome, and DKA.

Hyperphosphatemia can be a spurious finding in cases of hyperproteinemia, such as multiple myeloma, hyperlipidemia, hemolysis, or hyperbilirubinemia. Drawing of a blood sample from a line containing heparin is another cause of a falsely elevated phosphate level.

Box 117.12

Five Most Common Causes of Hyperphosphatemia

DECREASED PHOSPHATE EXCRETION
Acute and chronic renal failure

INCREASED RENAL TUBULAR REABSORPTION
Hypoparathyroidism
Thyrotoxicosis
Excess vitamin D administration

EXCESSIVE PHOSPHATE INTAKE
Phosphate enemas or laxatives
IV or oral phosphate administration

SHIFT OF PHOSPHATE FROM INTRACELLULAR TO EXTRACELLULAR SPACE
DKA
Tumor lysis
Rhabdomyolysis

SPURIOUS HYPERPHOSPHATEMIA
Paraproteinemia
Hyperbilirubinemia
Hemolysis
Hyperlipidemia

DKA, Diabetic ketoacidosis; IV, intravenous.

Clinical Features

Patients with hyperphosphatemia may present with multiple complaints related to electrolyte abnormalities, particularly hypocalcemia. Hyperphosphatemia causes hypocalcemia by precipitating calcium out of the blood and decreasing vitamin D production. It is a secondary hypocalcemia that can cause muscle cramping, tetany, and seizures. Chronic hyperphosphatemia can also lead to metastatic calcifications in joints, tissues, and arteries.

Management

Dietary restriction alone may suffice for control of hyperphosphatemia in patients with mild renal insufficiency, but it is inadequate for control in those with overt renal failure. Because most patients presenting with severe hyperphosphatemia also have hypocalcemia, treatment focuses on the correction of both. In patients with normal renal function, phosphate excretion can be increased by saline infusion coupled with loop diuretics. Hyperphosphatemia usually resolves in 6 to 12 hours in patients with normal renal function. In patients with hyperphosphatemia with renal failure, hemodialysis or peritoneal dialysis should be considered early in the management. Currently, phosphate control is initiated only when hyperphosphatemia occurs, but it may be beneficial to intervene earlier in patients with chronic kidney disease. The optimal method for control of serum phosphate in patients undergoing dialysis is unknown and may involve combinations of dietary modification and enhancement of phosphate clearance through longer dialysis sessions.

HYPOPHOSPHATEMIA

Principles

Hypophosphatemia is defined as mild (2 to 2.5 mg/dL), moderate (1 to 2 mg/dL), or severe (<1 mg/dL). Mild to moderately
hypophosphatemia is usually asymptomatic and, like hypomagnesemia, often goes unrecognized. Although most patients remain asymptomatic, severe hypophosphatemia may result in potentially life-threatening complications. Major clinical sequelae usually occur only in severe hypophosphatemia.

Symptoms of hypophosphatemia typically begin to be manifested at serum levels below 1.0 mg/dL. Acute hypophosphatemia is most commonly due to a rapid intracellular shift. Hyperventilation, glucose, insulin, volume expansion, and resolving acidosis can lead to hypophosphatemia by rapid intracellular shift. The many causes of hypophosphatemia include decreased phosphate intake or increased absorptive states, hyperventilatory states, hormonal and endocrine effects, medications, and disease states (Box 117.13). The ED patients most likely to have hypophosphatemia are those who are malnourished with alcohol withdrawal, acute hyperventilation, or sepsis and patients with DKA or alcohol ketoacidosis in whom reintroduction of insulin and glucose causes phosphate uptake into cells.

**Box 117.13**

Five Most Common Causes of Hypophosphatemia in the Emergency Department

**DECREASED INTAKE OR INCREASED ABSORPTIVE STATES**
- Chronic alcoholism
- Home parenteral nutrition
- AIDS
- Chemotherapy
- Vomiting
- Malabsorption syndromes
- Secretory diarrhea
- Vitamin D deficiency

**HYPERVENTILATORY STATES**
- Sepsis
- Alcohol withdrawal
- Salicylate poisoning
- Neuroleptic malignant syndrome
- Panic attacks
- DKA
- Hepatic coma

**HORMONAL AND ENDOCRINE EFFECTS**
- Insulin loading
- Glucose loading
- Exogenous epinephrine
- Hyperparathyroidism

**MEDICATIONS**
- Diuretics
- Chronic antacid ingestion
- Steroids
- Phosphate binders
- Xanthine derivatives
- Beta-agonists

**DISEASE STATES**
- Trauma
- Severe thermal burns
- Acute renal failure
- Gout

---

Clinical Features

Mild to moderate hypophosphatemia is usually asymptomatic, but major clinical manifestations can occur with severe hypophosphatemia. Because phosphate is an essential component to adenosine triphosphate, hypophosphatemia can affect a variety of organ systems and a wide variety of symptoms (Box 117.14). Patients with hypophosphatemia may present with nonspecific complaints including joint pain, myalgias, irritability, and depression. Severe hypophosphatemia can be manifested as seizures, arrhythmias, cardiomyopathy, insulin resistance, acute tubular necrosis, rhabdomyolysis, and acute respiratory failure.

Management

We recommend patients with phosphate levels below 2.0 mg/dL be given phosphate repletion; patients with levels below 1.0 mg/dL necessitate treatment. Because hypophosphatemia is often coupled with hypokalemia, patients with hypophosphatemia often require potassium repletion as well. Oral phosphorus, 250 to 500 mg twice daily, can be given to stable or asymptomatic patients. IV preparations are available as sodium phosphate (Na2PO4 and NaPO4) or potassium phosphate (K2PO4 and KPO4), and rate of infusion and choice of initial dosage should be based on severity of hypophosphatemia and presence of symptoms.

**Box 117.14**

Clinical Manifestations of Hypophosphatemia

**CENTRAL NERVOUS SYSTEM**
- Irritability
- Confusion
- Paresthesias
- Depression
- Dysarthria
- Seizure
- Coma

**CARDIOVASCULAR**
- Cardiomyopathy
- Depressed myocardial contractility
- Arrhythmias

**RESPIRATORY**
- Acute respiratory failure
- Depressed myocardial contractility

**GASTROINTESTINAL**
- Ileus, dysphagia

**HEMATOLOGIC**
- Depressed levels of 2,3-diphosphoglycerate and adenosine triphosphate
- Leukocyte dysfunction
- Hemolysis
- Platelet dysfunction

**RENAL**
- Acute tubular necrosis
- Metabolic acidosis
- Hypercalcemia

**ENDOCRINE**
- Insulin resistance
- Hyperparathyroidism

*AIDS, Acquired immunodeficiency syndrome; DKA, diabetic ketoacidosis.*
If the serum phosphorus concentration is less than 1.5 mg/dL (0.48 mmol/L), 1.3 mmol/kg of elemental phosphorous (up to a maximum of 100 mmol) can be given in three or four divided doses in a 24-hour period. For routine replacement, give 0.5 mL/hr K2PO4; this may be increased to 1 mL/hr in severe symptomatic patients. Each milliliter of K2PO4 contains 3 mmol of phosphorus and 4.4 mEq of potassium.

Typical replacement therapy provides approximately 1 g of phosphorus per day. Patients should be monitored for the development of hypocalcemia, hyperkalemia, and hyperphosphatemia while IV phosphate is administered, especially in patients with renal insufficiency. Patients with DKA are initially hypophosphatemic. However, no studies have shown significant benefit to routine phosphate therapy in DKA. Risks of routine treatment with phosphate include hyperphosphatemia, renal failure, hypocalcemia, and hypomagnesemia. In patients with severe malnutrition or significant hypophosphatemia, replacement can be considered, but never administer more than 60 mmol/day without reason.

If the serum phosphorus concentration is less than 1.5 mg/dL (0.48 mmol/L), 1.3 mmol/kg of elemental phosphorous (up to a maximum of 100 mmol) can be given in three or four divided doses in a 24-hour period. Patients with DKA are initially hypophosphatemic. However, no studies have shown significant benefit to routine phosphate therapy in DKA. Risks of routine treatment with phosphate include hyperphosphatemia, renal failure, hypocalcemia, and hypomagnesemia. In patients with severe malnutrition or significant hypophosphatemia, replacement can be considered, but never administer more than 60 mmol/day without reason.

**KEY CONCEPTS**

- Asymptomatic electrolyte abnormalities can usually be corrected slowly, but those that cause profound mental status changes or life-threatening arrhythmias require immediate correction to avoid cardiac arrest or seizures.
- IV calcium should be used only for hyperkalemic emergencies, defined as the following: widening QRS; sine wave; cardiac arrest believed to be due to hyperkalemia; or rapidly evolving electrocardiographic changes, from normal to development of tall peaked T waves and loss of the P wave. Acute, rapid rises in serum potassium concentration are rare but may be seen in tumor lysis syndrome, rhabdomyolysis, or massive hemolysis.
- After the critical decision about administration of calcium has been made, a beta2-agonist, insulin and glucose, normal saline, and bicarbonate (if the patient is acidic) can be given to shift potassium intracellularly.
- In treatment of hypokalemia, the physician should also replace magnesium sulfate, in addition to potassium, or the patient will excrete most of the infused potassium in the urine.
- Low serum potassium levels reflect a much greater total potassium deficit; correction of large deficits can require several days.
- Hypertonic saline should be reserved for severely hyponatremic patients (typically in the 100 to 110 mEq range) who present with coma, seizures, or focal neurologic deficits. Central pontine myelinolysis can occur if serum sodium concentration is raised rapidly by more than 10 to 12 mEq/day.

The references for this chapter can be found online by accessing the accompanying Expert Consult website.
A patient with end-stage renal disease misses dialysis and presents feeling weak. His 12-lead electrocardiogram (ECG) shows peaked T waves, absent P waves, and a QRS duration of 240 milliseconds. Which of the following is the next step in emergency department (ED) management?

A. Calcium chloride  
B. Furosemide  
C. Hemodialysis  
D. Insulin with glucose  
E. Neubulized albuterol

**Answer:** A. Calcium chloride is the first medication that should be administered in this patient with a widened QRS. The treatment of hyperkalemia is based on the clinical scenario combined with the 12-lead ECG and the laboratory potassium value. Evaluating the ECG of patients at risk for this electrolyte disturbance is critical because results of the serum potassium level can be delayed. Hyperkalemia can be rapidly progressive, and lifesaving interventions should be instituted at the earliest suspicion of toxicity. Intravenous (IV) calcium is used to stabilize the cardiac membrane by restoring the electrical gradient. Calcium increases the depolarization threshold and the calcium gradient across the cardiac membrane, quieting myocyte excitability and increasing cardiac conduction speed, thus narrowing the QRS.

A young pregnant woman with eclampsia is transferred to the emergency department (ED) on a magnesium sulfate drip. She is barely arousable and has slow respirations. On examination, she has diffuse crackles in her lungs and absent reflexes. After oxygen is provided and she is attached to a monitor, what is the best treatment?

A. Activated charcoal  
B. Calcium gluconate  
C. Glucagon  
D. Naloxone  
E. Sodium bicarbonate

**Answer:** B. Calcium gluconate is the medication of choice in patients with suspected hypomagnesemia. Patients with hypomagnesemia may present with flushing, nausea, vomiting, headache, and diminished deep tendon reflexes. Intravenous (IV) calcium therapy to reverse magnesium toxicity should be reserved for patients with life-threatening symptoms while dialysis is being arranged. Calcium directly antagonizes the neuromuscular and cardiovascular effects of magnesium and is recommended in hypotensive patients with respiratory depression and cardiac instability.
117.3. For which of the following patients would it be most appropriate to supplement potassium to keep serum levels above 4 mEq/L?
A. A 23-year-old woman with palpitations and no past medical history
B. A 42-year-old woman with poorly controlled diabetes mellitus
C. A 51-year-old man with hypertension, recently started on lisinopril
D. A 55-year-old man with history of coronary artery disease, chest pain, and premature ventricular complexes
E. A 68-year-old man with chronic bronchitis and fever

Answer: D. The 55-year-old patient is at highest risk for life-threatening complications from hypokalemia secondary to his underlying comorbidities. In patients with cardiac ischemia or heart failure, even mild to moderate hypokalemia increases the likelihood of cardiac arrhythmias secondary to potassium's effect on the action potential.

117.4. A malnourished man with a long history of chronic obstructive pulmonary disease is brought to the emergency department (ED) in respiratory distress. He receives bronchodilators, intravenous (IV) dextrose, and thiamine. He improves significantly, but then begins to complain of severe muscle aches, diffuse weakness, and the feeling that he cannot breathe deeply. Supplementation with which of the following might have prevented his new symptoms?
A. Calcium gluconate
B. Diazepam
C. Normal saline
D. Potassium phosphate
E. Sodium bicarbonate

Answer: D. Patients with hypophosphatemia may present with nonspecific complaints, including joint pain, myalgias, irritability, and depression. Severe hypophosphatemia can be manifested as seizures, arrhythmias, cardiomyopathy, insulin resistance, acute tubular necrosis, rhabdomyolysis, and acute respiratory failure. Because hypophosphatemia often presents with hypokalemia, phosphate repletion should be considered in conjunction with potassium administration.

117.5. A patient in diabetic ketoacidosis (DKA) receiving insulin and intravenous (IV) fluids develops diffuse muscle weakness and pain. Her cardiac monitor shows broad T waves, U waves, and frequent premature ventricular complexes. What therapy is indicated?
A. Calcium gluconate
B. Dextrose
C. Potassium chloride
D. Sodium bicarbonate
E. Sodium phosphate

Answer: C. Hypokalemia can be a dangerous complication during treatment of DKA, and potassium chloride should be administered to this patient demonstrating both clinical and diagnostic signs of hypokalemia. Administration of insulin may cause a reduction in serum potassium because of insulin's ability to stimulate the sodium-potassium adenosine triphosphatase (Na⁺, K⁺-ATPase) pump and move potassium intracellularly. If there is any suspicion for hypokalemia or a patient presents with generalized weakness, palpitations, or arrhythmias, an electrocardiogram (ECG) should be obtained. A flattened broad T wave can be seen in hypokalemia. U waves, which are small deflections after the T wave, may also be seen. Patients should have their potassium repleted to prevent further complications.

117.6. A 58-year-old man with history of small cell lung cancer is brought in for weakness and pleuritic chest pain. He is alert, with normal vital signs, nonfocal neurologic examination, and serum sodium concentration of 129 mEq/L. What is the most appropriate management of the hyponatremia?
A. Free water restriction
B. Hypertonic saline bolus
C. Intravenous (IV) furosemide
D. Normal saline bolus
E. Sodium chloride tablets

Answer: A. The patient with small cell lung cancer is demonstrating signs and symptoms of hyponatremia. Lung cancers, especially small cell cancer, can lead to the syndrome of inappropriate secretion of antidiuretic hormone (SIADH). The mainstay for treatment of euclidean hyponatremia is free water restriction. As the hypo-osmolality in SIADH results from a relative abundance of water in the intracellular and extracellular volumes and is maintained by a reduced ability to excrete water, the restriction of free oral water intake is usually the most effective therapy. For relatively asymptomatic patients with sodium values of 115 to 135 mEq/L, a trial of free water restriction to less than 0.8 mL/day to 1.25 L/day should be attempted.

117.7. A runner is brought in after collapsing during a race. He has been careful to drink at each mile marker. He has altered mental status and is combative even after 10 mg of diazepam. What is the most appropriate treatment after his witnessed tonic-clonic seizure?
A. 5% Dextrose solution
B. Fosphenytoin
C. Hypertonic saline
D. Lorazepam
E. Pentobarbital

Answer: C. This runner is demonstrating symptoms concerning for exercise-associated hyponatremia, the occurrence of hyponatremia during or up to 24 hours after prolonged physical activity. Hypertonic saline is indicated in severe cases of hyponatremia when a patient has alterations in mental status, focal neurologic findings, or seizures.
Glucose is derived from three sources—intestinal absorption from the diet, the breakdown of glycogen (glycogenolysis), and the formation of glucose from precursors (gluconeogenesis). 

Because plasma glucose is the predominant metabolic fuel used by the central nervous system (CNS), maintenance of the plasma glucose concentration is critical to survival. The CNS cannot synthesize glucose, store more than a few minutes’ supply, or concentrate glucose from the circulation. Brief hypoglycemia can cause profound CNS dysfunction, and prolonged severe hypoglycemia may cause cellular death. Glucose regulatory systems have evolved to prevent and correct hypoglycemia.

The plasma glucose concentration is normally maintained within a relatively narrow range, between 60 and 150 mg/dL, despite wide variations in glucose levels after meals and exercise. Glucose is derived from three sources—intestinal absorption from the diet, the breakdown of glycogen (glycogenolysis), and the formation of glucose from precursors (gluconeogenesis), including lactate, pyruvate, amino acids, and glycerol. After glucose ingestion, the plasma glucose concentration increases as a result of glucose absorption. Endogenous glucose production is suppressed, and the plasma glucose level rapidly declines in response to insulin to a level below the baseline.

Insulin. Insulin receptors on the beta cells of the pancreas sense elevations in the blood glucose concentration and trigger insulin release into the blood. For incompletely understood reasons, glucose taken by mouth causes more insulin release than parenteral glucose. Certain amino acids induce insulin release and even cause hypoglycemia in some patients. Sulfonylurea oral hypoglycemic agents work, in part, by stimulating the release of insulin from the pancreas.

The number of receptor sites helps determine the sensitivity of the particular tissue to circulating insulin. The number and sensitivity of receptor sites are also the primary factors in the long-term efficacy of the sulfonylurea oral hypoglycemic agents. Receptor sites are increased in glucocorticoid deficiency and may be relatively decreased in obese patients.

Under normal circumstances, insulin is rapidly degraded through the liver and kidneys. The half-life of insulin is 3 to 10 minutes in the circulation. Whereas insulin is the major anabolic hormone implicated in diabetes, glucagon is the major catabolic hormone in disorders of glucose homeostasis.

Although most tissues have the enzyme systems required to synthesize and hydrolyze glycogen, only the liver and kidneys contain glucose-6-phosphatase, the enzyme necessary for the release of glucose into the circulation. The liver is essentially the sole source of endogenous glucose production. Renal gluconeogenesis and glucose release contribute substantially to the systemic glucose pool only during prolonged starvation.

Glucose Regulatory Mechanisms. Maintenance of the normal plasma glucose concentration requires precise matching of glucose use with endogenous glucose production and dietary glucose intake. The regulatory mechanisms that maintain systemic glucose balance involve hormonal, neurohumoral, and autoregulatory factors. Glucose regulatory hormones include insulin, glucagon, epinephrine, cortisol, and growth hormone. Insulin is the main glucose-lowering hormone. Insulin suppresses endogenous glucose production and stimulates glucose use. Insulin is secreted from the beta cells of the pancreatic islets into the hepatic portal circulation and has important actions on the liver and peripheral tissues. Insulin stimulates glucose uptake, storage, and use by other insulin-sensitive tissues, such as fat and muscle.

Counterregulatory hormones include glucagon, epinephrine, norepinephrine, growth hormone, and cortisol. When glucose is not transported into the cells because of a lack of food intake or lack of insulin, the body perceives a fasting state and releases glucagon, attempting to provide the glucose necessary for brain function. Glucagon is released in response to hypoglycemia as well as to stress, trauma, infection, exercise, and starvation. It increases hepatic glucose production within minutes, although transiently.

Epinephrine both stimulates hepatic glucose production and limits glucose use through both direct and indirect actions mediated by α-adrenergic and β-adrenergic mechanisms. Epinephrine also acts directly to increase hepatic glycogenolysis and gluconeogenesis. It acts within minutes and produces a transient increase in glucose production but continues to support glucose production at approximately basal levels thereafter. Norepinephrine acts as a sympathetic nervous system (SNS) mediator.
exerts hyperglycemic actions by mechanisms similar to those of epinephrine, except that norepinephrine is released from axon terminals of sympathetic postganglionic neurons.

Pathophysiology

Type 1 diabetes results from a chronic autoimmune process that usually exists in a preclinical state for years. The classic manifestations of type 1—hyperglycemia and ketosis—occur late in the course of the disease, an overt sign of beta cell destruction. The most striking feature of long-standing type 1 diabetes is the nearly total lack of insulin-secreting beta cells and insulin, with the preservation of glucagon-secreting alpha cells, somatostatin-secreting delta cells, and pancreatic polypeptide-secreting cells.

Although the exact cause of diabetes remains unclear, research has provided many clues. Studies of the pathogenesis of diabetes mellitus have demonstrated that the cause of the disorder glucose homeostasis varies from individual to individual. This cause may determine the presentation in each patient. Individual patients are currently not studied for the source of their disease, except on an experimental basis. The goals of work in progress, however, are to identify who is susceptible to the development of diabetes and prevent diabetic emergencies and sequelae or prevent expression of the disease.

Types of Diabetes

The American Diabetes Association (ADA) defines four major types of diabetes mellitus—type 1 diabetes mellitus, type 2 diabetes mellitus, gestational diabetes, and diabetes due to secondary disease processes or drugs. The 1997 National Diabetes Data Group reported discontinued use of the terms insulin-dependent diabetes mellitus and non-insulin-dependent diabetes mellitus because they were confusing and clinically inaccurate. In addition, the use of Arabic numerals, 1 and 2, instead of Roman numerals is the standard. The most recent update to the standards of care for diabetes was published in January 2015. The diagnostic criteria for the diagnosis of diabetes were changed in 2010 from the previous standards of elevated fasting glucose concentration and abnormal result of the 2-hour oral glucose tolerance test (OGTT) to use of the hemoglobin A1c (HbA1c) value as the preferred confirmatory test. An HbA1c value above 6.5% is now considered diagnostic of diabetes. However, the fasting plasma glucose concentration and 2-hour OGTT are still considered valid, as is the presence of a random glucose measurement of more than 200 mg/dl in a nonfasting patient with symptoms of diabetes. Use of the fasting plasma glucose concentration may help identify patients at risk for diabetes—that is, the glucose concentration is elevated but does not cross the threshold for the diagnosis of diabetes.

Type 1 Diabetes Mellitus. Type 1 diabetes is characterized by an abrupt failure of insulin production with a tendency to ketosis, even in the basal state. Parenteral insulin is required to sustain life. From 85% to 90% of patients with type 1 diabetes demonstrate evidence of one or more autoantibodies implicated in the cell-mediated autoimmune destruction of the beta cells of the pancreas. The autoimmune destruction has multiple genetic predispositions and may be related to undefined environmental insults.

Type 2 Diabetes Mellitus. Patients with type 2 diabetes may remain asymptomatic for long periods and show low, normal, or elevated levels of insulin. Ketosis is rare in type 2 disease. Patients frequently have hypertriglyceridemia and a high incidence of obesity. No association exists with viral infections, islet cell autoantibodies, or human leukocyte antigen (HLA) expression. Hyperinsulinemia may be related to peripheral tissue resistance to insulin because of defects in the insulin receptor. Defects in muscle glycogen synthesis have an important role in the insulin resistance.

Gestational Diabetes. Gestational diabetes mellitus is characterized by an abnormal OGTT result that occurs during pregnancy and reverts to normal during the postpartum period or remains abnormal. The clinical pathogenesis is thought to be similar to that of type 2. The clinical presentation is usually nonketotic hyperglycemia during pregnancy. Screening is performed around the 24th to 28th week with a 75-g oral glucose load in a woman with no prior history of diabetes.

Diabetes of Other Causes. Myriad causes of diabetes have been identified, including chronic pancreatitis, cystic fibrosis, genetic defects in the beta cell or in insulin receptors, and chemical-induced (eg, Vacor; chemotherapeutic, antipsychotic, or antiretroviral medications). The management of diabetes due to these conditions is cause-specific and depends on whether the underlying pathophysiologic process more closely resembles type 1 or 2 diabetes.

Prediabetes. Impaired glucose tolerance (IGT) has been replaced by the term prediabetes to identify individuals at high risk for the development of diabetes. The pathogenesis of prediabetes is thought to be related to insulin resistance. This group is composed of persons whose plasma glucose levels are between normal and diabetic; they are at increased risk for diabetes and cardiovascular disease. Presentations of prediabetes include nonketotic hyperglycemia, insulin resistance, hyperinsulinism, and often obesity. Prediabetes is not associated with the same degree of complications of diabetes mellitus, and many of these patients have normal glucose tolerance spontaneously. However, each year, about 1% to 5% of patients with IGT will develop diabetes mellitus.

Epidemiology

The most recent data estimate that 9% of Americans and 12% of adults older than 20 years have diabetes. The incidence of diabetes in those younger than 20 years approaches as high as 45/100,000 by the teenage years. The type of diabetes depends on age; most of those younger than 10 years have type 1, whereas type 2 predominates in the 10- to 19-year-old group. Type 1 is less common than type 2. The peak age at onset of type 1 diabetes is 10 to 14 years, and approximately 1 of every 600 schoolchildren has this disease. In the United States, the prevalence of type 1 is approximately 0.26% by the age of 20 years, and the lifetime prevalence approaches 0.4%. The annual incidence among persons from birth to 16 years of age in the United States is 12 to 14/1 million population. The incidence is age-dependent, increasing from near-absence during infancy to a peak occurrence at puberty and another small peak at midlife.

The morbidity in diabetes is related primarily to its vascular complications. A mortality rate of 36.8% has been attributed to cardiovascular causes, 17.5% to cerebrovascular causes, 15.5% to diabetic comas, and 12.5% to renal failure.

Clinical Features

Type 1

The patient with type 1 diabetes is usually lean, younger than 40 years, and prone to ketosis. Plasma insulin levels are absent to low; plasma glucagon levels are high but suppressible with insulin, and patients require insulin therapy to treat their symptoms. The
onset of symptoms may be abrupt, with polydipsia, polyuria, polyphagia, and weight loss developing rapidly. In some cases, the disease is heralded by ketoacidosis. Myriad problems related to type 1 diabetes may prompt an ED visit, including acute metabolic complications, such as DKA, and late complications, such as cardiovascular or circulatory abnormalities, retinopathy, nephropathy, neuropathy, foot ulcers, severe infections, and various skin lesions.

Type 2
The patient with type 2 diabetes is usually middle-aged or older and overweight, with normal to high insulin levels. Insulin levels are lower than would be predicted for glucose levels, however, leading to a relative insulin deficiency. Type 2 patients demonstrate impaired insulin function related to poor insulin production, failure of insulin to reach the site of action, or failure of an end-organ response to insulin. Although most adult patients with type 2 are obese, 20% are not.

Symptoms in type 2 diabetes tend to begin more gradually than in type 1. The diagnosis of type 2 is often made by the discovery of an elevated blood glucose level on routine laboratory examination. Hyperglycemia may be controlled by dietary therapy, oral hypoglycemic agents, or insulin administration. Decompensation of disease usually leads to HHS rather than to ketoacidosis.

Diagnostic Testing

Serum Glucose Level
The diagnosis of diabetes can be established in one or more of four ways—random plasma glucose level above 200 mg/dL, fasting plasma glucose concentration above 126 mg/dL, 2-hour, 75-g postload OGTT higher than 200 mg/dL, or HbA1c value above 6.5%. In the absence of hyperglycemia with metabolic decompensation, these criteria should be confirmed by repeated testing on a different day. Confirmation can be made by the same test or two different tests (eg, fasting plasma glucose and HbA1c). A fasting value above 150 mg/dL is likely to distinguish diabetic from nondiabetic patients more accurately. Formal OGTTs are unnecessary except during pregnancy or in patients who are thought to have diabetes, but who do not meet the criteria for a particular classification. The World Health Organization and ADA have provided protocols for performing the OGTT.1

Glycosylated Hemoglobin
Measurement of glycosylated hemoglobin (HbA1c) is one of the most important ways to assess the level of glucose control. An elevated serum glucose level binds progressively and irreversibly to the amino-terminal valine of the hemoglobin β chain. The HbA1c measurement provides insight into the quality of glycemic control over time. Given the long half-life of red blood cells, the percentage of HbA1c is an index of glucose concentration of the preceding 6 to 8 weeks, with normal values approximately 4% to 6% of total hemoglobin, depending on the assay used. Levels in patients with poorly controlled disease may reach 10% to 12%. The ADA has recommended at least biannual measurements of HbA1c for the follow-up of all types of diabetes. The ADA currently sets an HbA1c value of less than 7% as a treatment goal.

Urine Glucose Level
Urine glucose measurement methods are of two types, reagent tests and dipstick tests. The reagent tests (eg, Clinitest) are copper reduction tests. The reagent tests are rarely used because they are difficult to perform, and the test material is toxic for ingestion or dermal exposure. Dipstick tests generally use glucose oxidase, which may also be affected by different substances. Dipsticks are inexpensive and convenient but may vary in their sensitivity and strength of reaction to a given concentration of glucose. Dipstick interpretation can vary significantly, depending on the observer and type of lighting. Both falsely high and falsely low urine glucose readings can also occur. With the plus system, 1+, 2+, 3+, and 4+ have different implications about urine glucose concentrations, depending on the brand of dipstick. The use of reflectance colorimeters to read dipsticks increases accuracy.

Urine Ketone Level
Urine ketone dipsticks use the nitroprusside reaction, which is a good test for acetoacetate but does not measure β-hydroxybutyrate. Although the usual ratio of acetoacetate to β-hydroxybutyrate in DKA is 1 : 2.8, it may be as high as 1 : 30, in which case the urine dipstick does not reflect the true level of ketosis. When ketones are in the form of β-hydroxybutyrate, the urine ketone dipstick may infrequently yield negative reactions in patients with significant ketosis.

Dipstick Blood Glucose Level
Dipsticks for testing the blood glucose level are clearly more accurate than urine dipsticks as a means of monitoring blood glucose concentration, but they also may be inaccurate. Hematocrits below 30% or above 55% cause inaccurately high or low readings, respectively, and a number of the strips specifically disclaim accuracy when used for neonates. Sensitivity of dipsticks to a variety of factors varies with the particular brand. The largest errors are in the hyperglycemic range. Dipstick readings rarely err more than 30 mg/dL when the actual concentration is below 90 mg/dL. Although specific glucose concentrations may not be accurately represented, blood glucose dipsticks are useful for estimating the general range of the glucose value. Reflectance meters increase the accuracy of the dipstick blood glucose level determination. The use of glucometers has supplanted the use of dipsticks in most clinical settings and tends to be fairly accurate, except, again, at the extremes of glucose levels (<30 mg/dL or >600 mg/dL). If maximum accuracy is desired, a laboratory blood glucose level should be determined.

Management

Approach to New-Onset Hyperglycemia in the Emergency Department
Patients often present to the ED with typical diabetic symptoms, such as polyuria, polydipsia, and polyphagia. Many have serum glucose concentrations above 200 mg/dL but are not ketogenic. Patients with newly diagnosed hyperglycemia with normal electrolyte values may be treated with intravenous (IV) hydration alone or with insulin, often reducing the glucose concentration to 150 mg/dL. In reliable patients whose initial glucose concentration is greater than 400 mg/dL, initiation of oral hypoglycemic therapy may be appropriate, with lifestyle modification. An HbA1c value should be obtained before initiation of therapy to confirm a diagnosis of diabetes and to establish a baseline.

Initial therapy with sulfonylureas is appropriate; glyburide (2.5–5 mg once daily) or glipizide (5 mg once daily) is recommended.12 Metformin may be initiated as well, at a dose of 500 mg daily; however, it lowers the blood glucose level on average only by about 100 mg/dL. Newly diagnosed diabetics frequently require additional agents to control their glucose concentration. Patients with kidney disease may have complications from use of
a sulfonylurea or metformin and will likely need insulin therapy. Follow-up should be stressed and warning signs of hypoglycemia discussed.

Management of Diabetes

Although emergency clinicians will rarely provide longitudinal care for diabetic patients, these patients present frequently to the ED, and we believe it is helpful for them to understand basic management principles and modern trends in the treatment of this important disease. The basic concepts of the diabetic diet remain unchanged, although many studies emphasize foods and medications that alter glucose absorption. Various high-fiber diets have improved glycemic control. The number of supplements or low–glycemic index snacks has risen in the last decade. Exercise continues to be a cornerstone of diabetes management, although care must be taken to balance it with appropriate calorie intake and medication use.

**Oral Hypoglycemic Agents.** Goals of diabetic management include lowering the hemoglobin A1c to less than 7% and maintenance of the fasting blood sugar level to within 90 to 130 mg/dL. When started on monotherapy, after 3 years, approximately 50% of patients need a second drug. There have been an increasing number of oral agents for hyperglycemia available in recent years. Some of these have serious side effects, requiring the emergency clinician to be familiar with these drugs. If these effects are expected to be prolonged, the patient may require observation. Categories of oral agents may be divided into those that increase the insulin supply, including sulfonylureas, secretagogues, and insulin itself. Medications that decrease insulin resistance include the biguanides and thiazolidinediones; drugs that reduce the rate of glucose absorption include α-glucosidase inhibitors. Oral hypoglycemic agents generally lower HbA1c levels by 0.5 to 1.5%. Metformin is generally used as the first-line agent for oral therapy. If the goal of lower HbA1c levels is not achieved, addition of a sulfonylurea or pioglitazone should be considered.

**Biguanides.** The ADA and European Association for the Study of Diabetes have recommended lifestyle changes, including weight control, at the time of diabetes diagnosis. Metformin (a biguanide) is the initial drug of choice because it does not induce weight gain, has low cost and good tolerability, and tends not to induce hypoglycemia. Used alone, metformin does not cause hypoglycemia, but is contraindicated in patients with renal insufficiency. Metformin is renally excreted and should be used cautiously if the serum creatinine level is over 1.4 in females or 1.5 in males.

Metabolic acidosis is always a concern with biguanides. Ideally, metformin should be withheld for 48 hours prior to the administration of iodinated contrast media. In the emergency setting, metformin should be withheld after contrast administration for 48 hours due to the risk of acidosis. It is advisable to check the serum creatinine level before resuming this medication after contrast administration or surgery. Metformin must be used with caution in patients with hypoxemia, pregnancy, heart failure, liver compromise, and alcohol abuse. These patients may be at risk for developing lactic acidosis, which has been associated with a 50% mortality rate.

**Sulfonylureas.** Developed in the 1940s, the sulfonylureas have historically been a mainstay of oral diabetes treatment. These drugs increase insulin secretion by binding to specific beta cell receptors. This class of drugs is especially useful for patients with early-onset, type 2 diabetes mellitus and fasting blood glucose levels less than 300 mg/dL. This class of drug is contraindicated in patients with a known allergy to sulfa agents. Patients with renal failure may be predisposed to hypoglycemia. Examples of sulfonylureas include glipizide (Glucotrol, Glucotrol XL), gliclazide (Amaryl), and glyburide (Diabeta, Glynase PresTab, Micronase). These interact with potassium channels in the beta cell membrane. The risk of hypoglycemia is greater in older adults and in those with impaired renal and hepatic function; they may be associated with weight gain. They generally lower the glucose level by 20%, and HbA1c levels by 1% to 2%. Glipizide is shorter acting and therefore less likely than the other sulfonylureas to induce prolonged hypoglycemia. However, for all sulfonylureas, there have been several case reports of delayed onset of hypoglycemia from 12 to 21 hours after ingestion, leading to general recommendations to observe the patient for a 24-hour period.

**Thiazolidinediones.** Thiazolidinediones reduce insulin resistance and are especially useful in patients who require large amounts of insulin and still lack adequate glucose control. They are associated with hepatotoxicity and require liver function monitoring. For this reason, troglitazone has been removed from the market; pioglitazone (Actos) and rosiglitazone (Avandia) remain approved for monotherapy. Cardiovascular risks, including myocardial infarction, may be higher with rosiglitazone. These agents may also be associated with weight gain, fluid retention, and heart failure. They increase insulin sensitivity and may be expected to reduce the HbA1c value by 0.5% to 1.4% points. They are contraindicated for patients with New York Heart Association class III or IV heart failure.

**α-Glucosidase Inhibitors.** The α-glucosidase inhibitors delay intestinal monosaccharide absorption and prevent complex carbohydrate breakdown; these agents include acarbose (Precose and generic) and miglitol (Glyset). They must be titrated to minimize gastrointestinal (GI) side effects and should not be used in patients with certain GI disorders. Liver function must be monitored because of dose-dependent hepatotoxicity. They should be taken with meals because they delay absorption of glucose. Side effects include abdominal pain, diarrhea, and flatulence from unabsorbed carbohydrates. They lower the HgbA1c by 0.5% to 0.8% points.

**Meglitinides.** The nonsulfonylurea secretagogues, the meglitinides, are similar to the sulfonylureas in action and mechanism. They bind to adenosine triphosphate–sensitive potassium channels of beta cells to increase insulin secretion. They have a rapid onset of action and should be taken before a meal, involve less risk of hypoglycemia, and are suitable for patients allergic to sulfa medications. The specific agents available are nateglinide (Starlix) and repaglinide (Prandin). These may be better for patients with impaired renal function due to their liver metabolism. Management of refractory hypoglycemia in these agents may be done in a manner similar to that for sulfonylures, with use of octreotide by bolus or infusion.

**Glucagon-Like Peptide Analogues and Agonists.** Glucagon-like peptide (GLP-1) analogues and agonists stimulate the release of insulin from pancreatic cells. Exanetide (Byetta) is US Food and Drug Administration (FDA)–approved for twice-daily subcutaneous injection in patients with type 2 diabetes who have not achieved satisfactory control with metformin, a sulfonylurea, pioglitazone, or lifestyle modifications. It lowers serum glucagon concentrations and slows gastric emptying. Liraglutide (Victoza) is also in this class. GLP itself has a half-life of only a few minutes. The GLP agonists bind to the GLP receptor on the pancreas and have a much longer half-life. Exanetide has been demonstrated to improve attainment of HbA1c goals, even when administered once weekly. Clinical experience with their toxicology is limited, but there have been episodes of hypoglycemia reported. Observation recommendations are not established but, given the long half-life of the medications, we recommend a period of at least 24 hours.

**Dipeptidyl Peptidase-4 Inhibitors.** Dipeptidyl peptidase-4 (DPP-4) inhibitors include sitagliptin (Januvia), saxagliptin...
Transplantation. Dapagliflozin is an oral hypoglycemic agent in the management of type 2 diabetes, which has been approved for use in patients with types 1 and 2 diabetes and may promote weight loss.

Amylin Analogue. Pramlintide, administered three times daily before meals, is an amylinomimetic agent, or amylin analogue, and decreases gastric emptying and glucagon secretion. It has been approved for use in patients with types 1 and 2 diabetes and may promote weight loss.

Sodium-Glucose Cotransporter 2 Inhibitors. Dapagliflozin (Farxiga), canagliflozin (Invokana), and SGLT2 are sodium-glucose cotransporter 2 inhibitors. SGLT2 is a protein that transports filtered glucose from the proximal renal tubule into tubular epithelial cells, enhancing urinary excretion levels of glucose. They may also lower blood pressure and induce some degree of weight loss.

Insulin. Certain principles apply to all insulins, such as their ability to enhance gluconeogenesis and lipogenesis and suppress glycogenolysis. Human insulins are available today as regular insulin and neutral protamine hagedorn (NPH). Regular insulin, which is used in the treatment of DKA, has an onset of action within 30 to 60 minutes and is typically dosed 30 to 45 minutes before a meal. Its duration of action is approximately 4 to 12 hours. NPH insulin (eg, Humulin, Novolin), being longer acting, is typically dosed 4 to 6 hours before a meal; it has a 12- to 24-hour duration of action and is administered two or three times daily. Regular and NPH insulin may be mixed together to lessen the number of daily injections.

More recently, insulin analogues have been developed. These entail modification of the terminal end of the A or B chain of the insulin molecule. The rapid-acting insulins currently on the market are glulisine, insulin lispro (Humalog), and insulin aspart (NovoLog); their onset of action is approximately 10 to 30 minutes and duration is 3 to 5 hours. They are typically administered 5 to 20 minutes before a meal. Long-acting insulin analogues are detemir (Levemir) and glargine (Lantus); their onset of action is 3 to 4 hours and their duration of action approaches 24 hours, similar to that of NPH. Insulin glargine and detemir, being long-acting but without a peak response, more closely mimic continuous pump infusion.

Although treatment for type 2 diabetes has traditionally started with oral agents, analogue insulin therapy has been recently advocated as an initial therapy for type 2 diabetes. Type 2 diabetes is associated with a decline of beta cell function over time, and intensive insulin therapy has been advocated early to rest the beta cells and possibly preserve their function over time. Starting patients on 10 units/day of glargine, with 6 units of aspart at mealtime, has been used as primary treatment for type 2 diabetes. Basal insulin titration algorithms from the ADA, American College of Endocrinology, Canadian Diabetes Association, and International Diabetes Federation have recommended initial starting dosages of 10 units/day, titrating upward by 1 to 3 units every 1 to 3 days, with a target HbA1c level below 6.5% to 7%.

Ultrafast-acting insulin analogues reduce postprandial glucose fluctuations and abnormalities. The intent is to match insulin absorption and action to food-related rises in the plasma glucose level. These basal insulin analogues may enable the time of administration of the insulin to vary widely. Although many emergency clinicians are more comfortable starting patients on oral hypoglycemic agents in the management of type 2 diabetes, more patients can be started on insulin as initial treatment for type 2 diabetes. Glargine, detemir, or NPH insulin may be initiated at 0.1 to 0.2 units/kg, or roughly 10 units/day, with follow-up within 3 to 4 days for dose adjustment. Unless the emergency clinician is particularly well versed in insulin therapy, this latter approach frequently involves the development of an outpatient protocol with a specialty consultant (eg, endocrinologist).

Pancreas Transplantation. Solid organ pancreas transplantation has become more common; several centers have performed combined pancreas and kidney transplants in those with end-stage kidney disease due to diabetic nephropathy. Transplantation ameliorates many secondary complications of diabetes, such as nephropathy, neuropathy, gastroparesis, retinopathy, and microvascular changes. The percentage of grafts functioning after 1 year and 1-year survival rate of patients are greater than 75% in selected medical centers. However, rejection, posttransplantation pancreatitis, and graft thrombosis, as well as other vascular and immunosuppression problems, continue to plague transplant recipients.

New Trends in Diabetes Management. Changes in the therapy of diabetes have recently included greater use of human insulin, which has prevented some of the adverse reactions to beef and pork products. Unfortunately, some patients demonstrate sensitivity reactions, even to human insulin. Some physicians are teaching their diabetic patients and families how to administer glucagon to treat severe hypoglycemia.

The initiation of immunosuppressive therapy at the initial diagnosis of type 1 diabetes can prolong the patient’s ability to secrete insulin. This beneficial effect, whether achieved by azathioprine or cyclosporine, is not usually sustainable. The potential side effects of immunosuppressive agents have precluded large trials in patients early in their disease. Prophylactic insulin therapy, nicotinamide, oral insulin, or glutamate decarboxylase and avoidance of cow’s milk may prevent or delay the onset of type 1 diabetes in patients at risk.

Glycemic control now involves improved technology and more widespread individual monitoring of daily insulin dosage adjustments. Diabetic patients with tight glycemic control benefit by limiting the progression of microvascular disease—neuropathy, renal disease, and certain types of retinopathy. However, they are more likely than other diabetic patients to experience hypoglycemic episodes.

Emergency clinicians and out-of-hospital care providers are encountering patients with insulin pumps. Insulin pumps are available, with each having a pump mechanism, reservoir for insulin, tubing, and indwelling subcutaneous needles. They are attached, usually with tapes, to the patient’s body and administer insulin at a regular adjustable rate. Most pumps also allow the patient to administer additional boluses of insulin, as necessary. These pumps support tight glycemic control and are acceptable to some patients. However, motivated patients can achieve equivalent control by adjusting daily injections. Insulin pumps are associated with a variety of problems, including hypoglycemia. More recently, a wearable, automated bionic bihormonal pancreas has been noted to improve mean glycemic levels, with less frequent hypoglycemic episodes among adults with type 1 diabetes mellitus. The bionic pancreas receives data from a continuous glucose monitor to control subcutaneous delivery of insulin and glucagon.

Because glucose rotates the polarization of light waves, new fiberoptic technology has been developed to determine the blood glucose level noninvasively. This technique may be applied to the insulin pumps of the future. Ultrafast-acting insulins and biosimilar insulins may also be available in the near future. An inhaled insulin (Afrezza) has recently been released, but has been
associated with coughing and may exacerbate symptoms of reactive airway disease.

Newer insulin analogues are being developed, such as degludec and U-500, which improve glycemic control without contributing to hypoglycemia. Agents in the DPP-4 inhibitor class have not been associated with weight gain. Therefore, pharmacologic agents offer the promise of improving glycemic control for longer periods, with fewer glycemic fluctuations, less weight gain, and less hypoglycemia. Other new areas of research have included agents that increase the urinary excretion of glucose or increase hepatic gluconeogenesis.

**DIABETIC KETOACIDOSIS**

**Principles**

**Pathophysiology**

DKA is a syndrome in which insulin deficiency and glucagon excess combine to produce a hyperglycemic, dehydrated, acidic patient, with profound electrolyte imbalance. All derangements producing DKA are interrelated and based on insulin deficiency (Fig. 118.1). DKA may be caused by cessation of insulin intake or by physical or emotional stress, despite continued insulin therapy. The effects of insulin deficiency may be mimicked in peripheral tissues by a lack of insulin receptors or insulin sensitivity at receptor or postreceptor sites. When the hyperglycemia becomes sufficiently marked, the renal threshold is surpassed, and glucose is excreted in the urine. The hyperosmolarity produced by hyperglycemia and dehydration is the most important determinant of the patient’s mental status.

Glucose in the renal tubules draws water, sodium, potassium, magnesium, calcium, phosphorus, and other ions from the circulation into the urine. This osmotic diuresis, combined with poor intake and vomiting, produces the profound dehydration and electrolyte imbalance associated with DKA (Table 118.1). Exocrine pancreatic dysfunction closely parallels endocrine beta cell dysfunction, producing malabsorption that further limits the body’s intake of fluid and exacerbates electrolyte loss.

In 95% of patients with DKA, the total sodium level is normal or low. Potassium, magnesium, and phosphorus deficits are usually marked. As a result of acidosis and dehydration, however,

*Per kilogram of body weight.*
the initial reported values for these electrolytes may be higher than actual body stores. Hypokalemia may also inhibit insulin release.

The cells, unable to receive fuel substances from the circulation, act as they do in starvation from other causes. They decrease amino acid uptake and accelerate proteolysis so that large amounts of amino acids are released to the liver and converted to two-carbon fragments.

Adipose tissue in the patient with DKA fails to clear the circulation of lipids. Insulin deficiency results in activation of a hormone-sensitive lipase that increases circulating free fatty acid (FFA) levels. Long-chain FFAs, now circulating in abundance as a result of insulin deficiency, are partially oxidized and converted in the liver to acetoacetate and β-hydroxybutyrate. Despite the increased pathologic production of ketones, the body acts as it does in any form of starvation to decrease the peripheral tissue’s use of ketones as fuel. The combination of increased ketone production with decreased ketone use leads to ketoacidosis.

Acidosis plays a prominent role in the clinical presentation of DKA. The acidic patient attempts to increase lung ventilation to rid the body of excess acid with Kussmaul’s breathing. Bicarbonate is used up in the process. Acidosis compounds the effects of ketosis and hyperosmolality to depress mental status directly.

Acidemia is not invariably present, even with significant ketoacidosis. Ketaalkalosis has been reported in diabetic patients vomiting for several days and in some with severe dehydration and hyperventilation. The finding of alkalemia, however, should prompt consideration of alcoholic ketoacidosis, in which alkalemia is much more common. Although these cases are rare, if there is concern for a mixed acid-base disorder, an arterial blood gas sample should be obtained instead of a venous gas sample to delineate the metabolic abnormalities present further.

Causes

DKA most commonly occurs in patients with type 1 diabetes and is associated with inadequate administration of insulin, infection, or myocardial infarction. DKA can also occur in type 2 diabetics and may be associated with any type of stress, such as sepsis or GI bleeding. Approximately 25% of all episodes of DKA occur in patients whose diabetes was previously undiagnosed.

Clinical Features

Clinically, most patients with DKA complain of a recent history of polydipsia, polyuria, polyphagia, visual blurring, weakness, weight loss, nausea, vomiting, and abdominal pain. Approximately 50% of these patients, especially children, report abdominal pain. In children, this pain is usually idiopathic and probably caused by gastric distention or stretching of the liver capsule; it resolves as the metabolic abnormalities are corrected. In adults, however, abdominal pain more often signifies true abdominal disease that may be triggering the DKA.

Physical examination may or may not demonstrate a depressed sensorium. Typical findings include tachypnea with Kussmaul’s breathing, tachycardia, frank hypotension or orthostatic blood pressure changes, odor of acetone on the breath, and signs of dehydration. An elevated temperature is rarely caused by DKA itself and suggests an inciting infection.

Diagnostic Testing

Initial tests allow preliminary confirmation of the diagnosis and initiation of therapy (Table 118.2). Subsequent tests are carried out to determine more specifically the degree of dehydration, acidosis, and electrolyte imbalance and reveal the precipitant of DKA.

Laboratory studies should include serum glucose, electrolyte, and blood gas levels. Although serum ketone levels are frequently measured, they are not necessary to diagnose DKA and make be elevated in non-DKA states (eg, starvation ketosis from inadequate utilization of glucose stores) or dehydration. If determination of the pH is the sole concern, venous blood gas samples correlate well with arterial pH. An arterial blood gas sample should be tested if there is concern for the adequacy of respiratory compensation or concern for a mixed acid-base disorder (eg, concomitant metabolic alkalosis from vomiting). Winter’s formula (expected PaCO₂ = [1.5 × serum HCO₃⁻] + [8 ± 2]) can be applied to determine if there is appropriate respiratory compensation or the presence of multiple acid-base disorders. The glucose level is usually elevated above 350 mg/dL; however, euglycemic DKA (blood glucose level ≤ 300 mg/dL) has been reported in up to 18% of patients. Blood gas measurement usually reveals a low pH, with the aforementioned rare exception of a concomitant alkalemia, which may result in a pseudonormalization of the pH. Metabolic acidosis with an anion gap is primarily the result of elevated plasma levels of acetoacetate and β-hydroxybutyrate, although lactate, FFAs, phosphates, volume depletion, and several medications can also contribute. Rarely, a well-hydrated patient with DKA may have a pure hyperchloremic acidosis with no anion gap if they have been aggressively rehydrated with normal saline. Again, although rare, there have been case reports of a normal anion gap in a patient with DKA. This occurred if the vomiting was sufficient to cause a concomitant metabolic alkalosis to such a degree that the pH and bicarbonate level appear to be in the normal range because the combined derangements result in false normal-appearing laboratory values. If an immediate potassium level is not available through blood gas analysis, an electrocardiogram can reveal signs of hyperkalemia or hypokalemia. Initial serum potassium levels are typically normal or high in DKA due to intracellular potassium shifting out of cells in exchange for elevated serum hydrogen ions. However, as potassium is lost in the urine, the total body potassium usually declines by several hundred milliequivalents. This, in combination with the insulin doses administered in DKA, can result in life-threatening hypokalemia. A basic metabolic panel should be obtained to evaluate renal function, acid-base status, and glucose and electrolyte levels. Because magnesium and potassium deficits are common in DKA, we recommend determining these levels as well. Urinalysis, in addition to the presence of ketones, may also help confirm a urinary tract infection as a precipitant of DKA. Use of blood or urine cultures should be determined by the clinical picture.

The serum sodium level is often misleading in DKA; it is often low in the presence of significant dehydration because it is strongly affected by hyperglycemia, hypertriglyceridemia, salt-poor fluid intake, increased GI and renal losses, and insensible loss. When hyperglycemia is marked, water flows from the cells...
into the vessels to decrease the osmolar gradient, thereby creating dilutional hyponatremia. Elevated lipid levels cause a pseudohyponatremia by decreasing the fraction of serum that is water. Newer autoanalyzers remove triglycerides before assay, thus eliminating this artifact. The true value of the sodium level may be approximated by adding 1.6 mEq/L to the sodium value on the laboratory report for every 100-mg/dL glucose above the norm. Thus, if the laboratory reports a serum sodium level of 130 mEq/L and blood glucose level of 700 mEq/L, the total serum sodium level is more accurately assessed to be 139.6 mEq/L.

Acidosis and the hyperosmolarity induced by hyperglycemia shift potassium, magnesium, and phosphorus from the intracellular to extracellular space. Dehydration results in hemococoncentration, which contributes to normal or high initial serum potassium, magnesium, and phosphorus readings in DKA, even with profound total body deficits. The effect of acidosis on the serum potassium level determination can be corrected by subtracting 0.6 mEq/L from the laboratory potassium level for every 0.1-decrease in pH noted in the arterial blood gas analysis. Thus, if the potassium level is reported as 5 mEq/L and the pH is 6.94, the corrected potassium value would be only 2 mEq/L, representing severe hypokalemia. As insulin is administered and the hydrogen ion concentration decreases, the patient needs considerable potassium replacement. Finally, hyperglycemia and the anion gap have significant effects on the plasma potassium concentration, independent of acidosis. No conversion factor has been developed for the estimation of true magnesium levels, although initial values may be high.

All laboratory determinations must be interpreted with caution. Serum creatinine level determinations made by autoanalyzer may be falsely elevated. Leukocytosis more closely reflects the degree of ketosis than the presence of infection. Only the elevation of band neutrophils has been demonstrated to indicate the presence of infection, with a sensitivity of 100% and specificity of 80% from a single small retrospective study. Historically, the diagnosis of pancreatitis in a patient with DKA could be confused by the elevation of amylase levels in DKA. Given the strength of the current literature demonstrating greater specificity of lipase for the diagnosis of pancreatitis, lipase should be the blood test of choice if pancreatitis is a concern.

Differential Diagnoses

Alcoholics, especially those who have recently abstained from drinking, with Kussmaul's breathing, fruity odor to the breath, and acidic arterial blood gas values may have alcoholic ketoacidosis. These patients may be euglycemic or hypoglycemic, and a large part of their acidosis is often caused by the unmeasured β-hydroxybutyric acid. Alcoholic ketoacidosis accounts for approximately 20% of all cases of ketoacidosis. Ketoacidosis can also develop with fasting, commonly in the third trimester of pregnancy and in nursing mothers who do not eat.

The differential diagnosis for DKA is broad and includes any entity that may cause elevated anion gap acidosis, ketosis, or both. The presence of DKA should not exclude investigation for other causes of anion gap metabolic acidosis, such as sepsis, poisoning, or lactic acidosis, because physiologic stress from one of these other causes can precipitate DKA.

Management

The comatose patient, especially if vomiting, requires intubation. Once the patient is intubated, maintenance of hyperventilation prevents worsening acidosis. The patient in hypovolemic shock requires aggressive fluid resuscitation with isotonic crystalloids rather than vasopressors; consider other possible causes of shock (eg, sepsis or myocardial dysfunction secondary to myocardial infarction). Bedside ultrasonography may be of benefit in excluding other causes of hypotension and evaluating the volume status of an individual patient. Although it is not routinely used in the ED setting, in cases in which the volume status is difficult to ascertain because of complex underlying physiologic derangements (eg, congestive heart failure, renal failure), the rapid ultrasound for shock and hypotension examination (see Chapter e5) or invasive hemodynamic monitoring may be required to guide fluid therapy.

When hyperglycemia, ketosis, and acidosis have been established, fluid, electrolyte, and insulin therapy should be initiated (Box 118.1).

Insulin

DKA cannot be reversed without insulin, and insulin therapy should be initiated as soon as the diagnosis is certain. There have been no randomized trials comparing insulin with placebo or other therapies for DKA. However, the mortality from DKA was 90% in historical controls before the development of exogenous insulin and 50% after insulin was introduced; with appropriate supportive therapy, it has reached the current levels of 5% to 7%.

Although the dosing of insulin infusions has been established, the value of an IV bolus before the infusion remains controversial.

**Box 118.1**

**Summary of Treatment of Diabetic Ketoacidosis**

Identify diabetic ketoacidosis—serum glucose, electrolyte, and ketone levels and arterial blood gas analysis; also obtain complete blood count with differential, urinalysis, chest radiograph, and electrocardiogram, if indicated.

- Supplement insulin.
  - Insulin replacement—0.1 unit/kg/hr regular insulin IV
  - Change IV solution to D₅W/0.45% normal saline (NS) when glucose concentration is ≤300 mg/dL.
- Rehydrate.
  - 1–2 L NS IV during 1–3 hours
  - Children—20 mL/kg NS during first hour
- Correct electrolyte abnormalities.
  - Sodium—correct with administration of NS or 0.45% NS.
  - Potassium—ensure adequate renal function. Add 20–40 mEq KCl to each liter (when serum potassium < 5.5 mEq/L) of fluid until ketoacidosis is corrected and potassium is normalized. (Do not give insulin until potassium 3.3 mEq/L or greater.)
  - Phosphorus—usually unnecessary to replenish.
  - Magnesium—correct with 1–2 g MgSO₄. Serum magnesium levels may not correlate with body stores.
- Correct acidosis.
  - Administer IV fluids and insulin.
  - Search for and correct underlying precipitant.
  - Monitor progress and keep meticulous flow sheets.
  - Vital signs
  - Fluid intake and urine output
  - Serum glucose, K⁺, Cl⁻, HCO₃⁻, CO₂, pH
  - Amount of insulin administered
- Admit to hospital or intensive care unit.
  - Consider outpatient therapy in children with reliable caregiver
  - Initial pH ≥ 7.35
  - Initial HCO₃⁻ ≥ 20 mEq/L
  - Can tolerate oral fluids
  - Resolution of symptoms after treatment in emergency department
  - No underlying precipitant requiring hospitalization
and is no longer routinely recommended. More recently, in selected patients with mild DKA, the subcutaneous or intramuscular administration of insulin has been proven safe and as effective as IV administration of insulin. In selected cases with good outpatient follow-up, treatment of DKA with intermittent bolus dosing of regular insulin by the subcutaneous or intramuscular route without admission has also been shown to be safe. Such a strategy requires a well-hydrated, mildly acidemic patient who is well versed in his or her disease management and has excellent outpatient follow-up. Poor perfusion may hamper the absorption of intramuscular or subcutaneous insulin, resulting in erratic absorption, making IV infusion the route of choice in sicker DKA patients. The current initial therapy of choice, as recommended by the ADA, is regular insulin infused at 0.1 units/kg/hr up to 5 to 10 units/hr, mixed with IV fluids.

Children with DKA pose additional management challenges. Whereas the general principles of fluid and electrolyte replenishment in concert with insulin therapy remain the same, controversy exists about the dosing and administration of fluids and insulin because of concerns related to the risk of inducing cerebral edema in children with DKA. Despite frequently voiced concerns about this complication, it remains rare, with an overall incidence of 1% in pediatric DKA patients. Virtually all current evidence supporting the contention that the use of higher doses of insulin and aggressive fluid resuscitation contribute to the development of cerebral edema has come from retrospective reviews and small case studies. The best available evidence shows associations only with lower PaCO₂ and higher blood urea nitrogen levels, indicating that severity of disease, rather than treatment interventions, plays the most significant role. DKA-related cerebral edema is more likely in children younger than 5 years, and good prospective data are needed to help guide recommendations. Currently, there is an ongoing clinical trial to assess risk and outcomes prospectively (clinicaltrials.gov). Given currently available data, patients should be carefully monitored and receive mannitol at the earliest suspicion of cerebral edema.

Because the half-life of regular insulin is 3 to 10 minutes, insulin should be administered IV by constant infusion rather than by repeated bolus. When the blood glucose concentration has dropped to 250 to 300 mg/dL, adding dextrose to the IV fluids reduces the risk of iatrogenic hypoglycemia and cerebral edema caused by rapid shifts in osmolarity. In patients with euglycemic DKA, dextrose should be added to the IV fluids at the start of insulin therapy. Insulin resistance occurs rarely in diabetic patients and requires an increase in dosage for a satisfactory response to be obtained. Resistance may be caused by obesity or accelerated insulin degradation.

Intravenous Fluids

The severely dehydrated adult patient is likely to have a fluid deficit of 3 to 5 L. No uniformly accepted formula exists for the administration of fluid in this disorder. If the patient is in hypovolemic shock, isotonic crystalloid solution should be given as rapidly as possible in the adult or in boluses of 20 mL/kg in the child until a systolic pressure of 80 mm Hg is obtained. There is no consensus regarding the ideal fluid to use; concerns have been raised with the use of large amounts of normal saline exacerbating metabolic acidosis. At least one small trial has studied the use of a balanced crystalloid solution (Plasmalyte) in DKA, with reports of more rapid restoration of normal physiologic parameters.

In the adult who has marked dehydration in the absence of clinical shock or heart failure, 1 L of fluid may be administered in the first hour. In general, 2 L of fluid resuscitation during the first 1 to 3 hours is followed by a slower infusion of a hypotonic solution, such as 0.45% normal saline solution. DKA patients without extreme volume depletion may be successfully treated with a lower volume of IV fluid replacement. An initial bolus of 20 mL/kg during the first hour is the usual fluid resuscitation therapy for a child. The fluid rate should be adjusted according to age, cardiac status, and degree of dehydration to achieve a urine output of 1 to 2 mL/kg/hr.

Fluid resuscitation alone may help lower hyperglycemia. Because a low level of circulating insulin may be present, increased perfusion may transport insulin to previously unreached receptor sites. In addition, a large volume of glucose may be cleared by the kidneys in response to improved renal perfusion. The mean plasma glucose concentration has been noted to drop by 18% after the administration of saline solution without insulin.

Acidosis also decreases after fluid infusion because increased perfusion improves tissue oxygenation and diminishes the formation of lactate. Increased renal perfusion promotes renal hydrogen ion loss, and the improved action of insulin in the better hydrated patient inhibits ketogenesis. Although fluid administration decreases the serum glucose concentration and improves acidosis, the underlying deficiency in DKA still requires administration of insulin for correction of ketoacidosis.

Potassium

Potassium replacement is invariably needed in DKA. The initial potassium level is often normal or high, despite a large deficit because of severe acidosis. Potassium levels often plummet with correction of acidosis and administration of insulin. Once potassium levels reach 5.0 to 5.5 mEq/L and the patient is making urine, potassium should be administered while monitoring renal function. In patients with relatively lower serum potassium concentration at presentation (3.3 to 5.0 mEq/L), hypokalemia may become life-threatening when insulin therapy is administered; therefore, IV administration of potassium in concentrations of 20 to 40 mEq/L should be given with insulin administration. In patients with hypokalemia (<3.3 mEq/L), insulin should only be initiated once potassium has been replaced to achieve levels of 3.3 mEq/L or higher. The primary rationale for such conservative recommendations regarding potassium administration is that serum levels do not correlate with total body stores in the DKA patient, and the potassium level can drop more rapidly than anticipated with administration of insulin.

It was once believed that there was always a phosphorus deficit in DKA. As a result, after initial potassium administration was completed with potassium chloride, potassium phosphate was used for follow-up potassium administration to correct the phosphorus deficit. There is no scientific evidence to support this practice, and only isolated case reports have supported concerns about clinically significant hypophosphatemia in DKA. If the measured serum phosphorus level is low, it should be replaced with potassium phosphate.

Magnesium

Magnesium deficiency is a common problem in patients with DKA without renal disease. Both the initial pathophysiologic process and therapy for DKA induce profound magnesium diuresis. Magnesium deficiency may exacerbate vomiting and mental changes, promote hypokalemia and hypocalcemia, and/or induce fatal cardiac dysrhythmia. If there is concern for hypomagnesemia, we recommend adding magnesium to the IV fluids, with the typical adult patient requiring 1 to 3 g for repletion.

Acidosis

In the past, sodium bicarbonate was recommended for severely acidemic patients (pH < 7.0). However, research has demonstrated...
worse outcomes for patients receiving bicarbonate, including exacerbation of electrolyte deficits such as hypokalemia, delaying clearing of ketosis, paradoxical worsening of acidosis in the CSF due to suppression of respiratory compensations and preferential permeability of the blood-brain barrier to CO₂. Unless needed to stave off impending cardiac arrest in a severely acidemic patient, we do not recommend routine bicarbonate administration.

Complications

The precipitating causes of DKA may have associated morbidity and mortality rates equal to or worse than those of DKA itself. These include iatrogenic causes, infection, and myocardial infarction. Morbidity in DKA is largely iatrogenic—hypokalemia from inadequate potassium replacement, hypoglycemia from inadequate glucose monitoring, failure to replenish glucose in IV solutions when the serum glucose concentration drops below 250 to 300 mg/dL, alkalosis from overaggressive bicarbonate replacement, and pulmonary edema from overaggressive hydration.

The mortality rate in treated DKA is approximately 5% to 7%. The primary causes of death remain infection, especially pneumonia, arterial thromboses, and shock. The decrease in the mortality rate has demonstrated that appropriate therapy can make a difference. Cerebral edema remains an important cause of morbidity and mortality in children with DKA.

Cerebral edema should be considered when the patient in DKA becomes altered or lapses into coma after the reversal of acidosis. Cerebral edema generally occurs 6 to 10 hours after the initiation of therapy; there are no warning signs, and the associated mortality rate is 90%.

Cerebral edema is less common in adults or children older than 5 years and appears to be most strongly associated with severity of illness (acidemia and azotemia), although subclinical cerebral edema in children is probably common. Furthermore, subclinical cerebral edema may precede or follow the onset of therapy, raising the question of whether it is caused by therapy or is simply a manifestation of the basic pathophysiologic mechanisms of DKA. The treatment of cerebral edema is largely supportive and outcomes are poor. No large clinical trials have identified effective treatment, although some authors recommend mannitol. Steroids have not been shown to be effective.

Disposition

Most patients with DKA require hospital admission, often to the intensive care unit. The use of observation units to manage uncomplicated DKA in selected patients has been shown to be effective (see Chapter e6). All pregnant diabetic patients in DKA require admission and consultation with an endocrinologist and obstetrician specializing in the care of high-risk pregnancies. Some children (initial pH ≥ 7.35; bicarbonate ≥ 20 mEq/L) with resolution of findings who can tolerate oral fluids after 3 or 4 hours of treatment may be discharged home with a reliable caregiver. Patients who have mild DKA may be treated on an outpatient basis if the patient or parent is reliable, underlying causes do not require inpatient therapy, and close follow-up is pursued.

HYPERGLYCEMIC HYPEROSMOLAR STATE

Principles

HHS represents a syndrome of acute diabetic decompensation characterized by marked hyperglycemia, hyperosmolality, dehydration, and decreased mental function that may progress to frank coma. The terminology has changed recently from the former term hyperglycemic hyperosmolar nonketotic coma because some patients have mild degrees of ketosis, and coma is not universally present. Ketoacidosis is generally minimal or absent, although metabolic acidosis from another source, such as lactic acidosis from sepsis or uremia from acute renal failure, may be present. Focal neurologic signs may be present, or there may be a global encephalopathy. DKA and HHS may occur together.

Pathophysiology

As with DKA, the pathophysiologic mechanisms of HHS vary with the particular patient. Because most patients with HHS are older adults, decreased renal clearance of glucose produced by the decline of renal function with age often contributes to the illness. Decreased insulin action results in glycogenolysis, gluconeogenesis, and decreased peripheral uptake of glucose. The hyperglycemia pulls fluid from the intracellular into the extracellular space, transiently maintaining adequate perfusion. Soon, however, this fluid is lost in a profound osmotic diuresis, limited finally by hypotension and a subsequent drop in the glomerular filtration rate (GFR). The urine is extremely hypotonic, with a urine sodium concentration between 50 and 70 mEq/L, compared with 140 mEq/L in extracellular fluid. This hypotonic diuresis produces profound dehydration, leading to hyperglycemia, hypernatremia, and associated hypertonicity. Often, the patient is prevented from taking in adequate fluids because of stroke, Alzheimer’s disease, or other diseases, greatly exacerbating the dehydration.

The reason for the absence of ketoacidosis in HHS is unknown. FFA levels are lower than in DKA, thus limiting the substrates needed to form ketones. The most likely reason for the blunted counterregulatory hormone release and lack of ketosis seems to be the continued secretion of tiny amounts of insulin that block ketogenesis.

Causes

HHS is a syndrome of severe dehydration that results from a sustained hyperglycemic diuresis in which the patient is unable to drink sufficient fluids to offset the urinary losses. The full-blown syndrome does not usually occur until volume depletion has progressed to the point of decreased urine output.

HHS is most common in geriatric patients with type 2 diabetes, but has been reported in children with type 1 diabetes. HHS may occur in patients who are not diabetic, especially after burns, parenteral hyperalimentation, peritoneal dialysis, or hemodialysis.

Clinical Features

The prodrome of HHS is significantly longer than that of DKA. Clinically, extreme dehydration, hyperosmolality, volume depletion, and CNS findings predominate. If they are awake, patients may complain of fever, thirst, polyuria, or oliguria. Approximately 20% of patients have no known history of type 2 diabetes. The most common associated diseases are chronic renal insufficiency, gram-negative pneumonia, GI bleeding, and gram-negative sepsis. Approximately 85% of patients have underlying renal or cardiac impairment as a predisposing factor. Arterial and venous thromboses are common and often complicate the picture.

The patient often exhibits orthostatic hypotension or frank hypotension, tachycardia, and fever, with signs of marked dehydration. The depression of the sensorium correlates directly with the degree and rate of development of hyperosmolality. Some patients have a normal mental status. Neurologic issues are common in HHS. Whereas a decreased level of consciousness is the most common neurologic finding, seizures, stroke syndromes,
and movement disorders have been reported in various case series. Whether HHS is the cause of or result of these disorders is unclear, and there is no current evidence to recommend the prophylactic use of antiepileptics or antithrombotic agents in HHS patients.

**Diagnostic Testing**

Laboratory findings usually reveal a blood glucose level above 600 mg/dL and serum osmolarity above 350 mOsm/L. The blood urea nitrogen concentration is invariably elevated. Although patients with HHS do not have a ketoacidosis caused by diabetes, they may have a metabolic acidosis secondary to some combination of lactic acidosis, starvation ketosis, and retention of inorganic acids attributable to renal hyperperfusion.

The patient with HHS typically has a more profound electrolyte imbalance than the patient with DKA. Levels of potassium, magnesium, and phosphorus may seem initially high, even in the presence of a marked total deficit. In the absence of acidemia, however, the discrepancy between the initial electrolyte reading and body stores is less than that of DKA. Initial serum sodium readings are inaccurate because of hyperglycemia.

**Differential Diagnoses**

The differential diagnosis of HHS is identical to that of DKA. In addition, diabetic patients receiving chlorpropamide are subject to water intoxication with dilutional hyponatremia, which may be manifested as coma without acidosis that is clinically indistinguishable from HHS. The patient with HHS who has a sharply depressed sensorium may not be initially distinguishable from the patient with profound hypoglycemia. When the blood glucose concentration cannot be rapidly checked, the immediate administration of one ampule of D$_{50}$W minimally worsens HHS and may be lifesaving for patients with hypoglycemia.

**Management**

The fluid, electrolyte, and insulin regimens for the initial resuscitation in HHS are subject to the same controversies as the therapies for DKA (see Box 118.1). There have been varying recommendations about which IV fluids to administer, generally based on calculations of water deficits. There have been no well-done randomized trials comparing isotonic versus hypotonic fluid resuscitation; use of an isotonic crystalloid is a reasonable choice in the volume-depleted patient. Cerebral edema has been noted in isolated case reports in adults, especially with glucose levels above 700 mg/dL. An association between IV fluid resuscitation and cerebral edema has not been shown in the literature; previous reports of this association may have been due to the confounder that it is seen in sicker patients who often receive more aggressive fluid resuscitation.

**Intravenous Fluids**

For patients in hypovolemic shock, initial IV fluid infusion is given as rapidly as possible. Glucose should be added to resuscitation fluids when the blood glucose level drops below 300 mg/dL. Because many HHS patients are older adults with coexisting disease, such as congestive heart failure and renal failure, noninvasive or invasive forms of hemodynamic monitoring may be required to guide fluid administration when there is clinical suspicion of pulmonary edema or volume overload.

**Electrolytes**

Measurement of serum electrolyte levels should be used to guide replacement in the HHS patient. In particular, because the degree of acidosis is generally less, potassium levels more accurately reflect total body stores than they do in DKA.

**Insulin**

The pathophysiologic mechanisms of HHS are different from those of DKA, and there is usually enough basal insulin function to prevent frank ketoacidosis. Therefore, a continuous IV insulin infusion is not required in these patients, as it is with DKA. However, there are times when the use of an IV insulin infusion may help lower the glucose concentration in a more controlled fashion, particularly in patients with very high glucose levels (>700 mg/dL) or those who are severely hypoperfused, in whom intramuscular or subcutaneous insulin absorption may be erratic. If an IV insulin infusion is used, it should be done at an infusion rate similar to that for DKA (0.1 unit/kg/hr).

**Other Considerations**

A vigorous search for the underlying precipitant of HHS should be pursued. Response to therapy should be followed in the manner described for patients in DKA. Phenytoin (Dilantin) is contraindicated for the seizures of HHS because it is often ineffective and may impair endogenous insulin release. Admitted patients should be given low-dose subcutaneous heparin to lessen the risk of thrombosis, which is increased by the volume depletion, hyperviscosity, hypotension, and inactivity associated with HHS.

**Acute Complications**

Reasons for high morbidity and mortality rates are not always clear, but many patients with HHS are older adults who have underlying cardiac and renal disease. Pediatric HHS differs from adult HHS in that children have a much higher incidence of fatal cerebral edema. Other causes of morbidity and mortality are similar to those described for DKA. The mortality rate of treated HHS patients has been 40% to 70% in the past but now ranges from 8% to 25%.

**Disposition**

In general, patients with HHS require hospitalization for IV hydration, glucose control, and evaluation of precipitating and complicating conditions.

**Late Complications of Diabetes**

Late complications of diabetes cause significant morbidity and mortality and develop approximately 15 to 20 years after the onset of overt hyperglycemia. The Diabetes Control and Complications Trial has shown that tight glycemic control significantly reduces the risk of microvascular disease, such as microalbuminuria (the earliest sign of nephropathy), neuropathy, and retinopathy, but at the expense of greatly increasing the risk of recurrent hypoglycemia.

**Vascular Complications**

Diabetes is associated with an increased risk for atherosclerosis and thromboembolic complications, which are a major cause of morbidity and premature death. The cause of accelerated atherosclerosis is unknown, although it is probably related to oxidized low-density lipoprotein and increased platelet activity. Atherosclerotic lesions are widespread, causing symptoms in many organ systems. Coronary artery disease and stroke are common. Diabetic patients have an increased incidence of so-called silent myocardial infarction, complicated myocardial infarctions, and congestive
Diabetic Nephropathy

Renal disease is a leading cause of death and disability in diabetic patients. Approximately 50% of cases of end-stage renal disease in the United States is caused by diabetic nephropathy. The appearance of microalbuminuria correlates with the presence of coronary artery disease and retinopathy. Azotemia generally does not begin until 10 to 15 years after the diagnosis of diabetes. Progression of renal disease is accelerated by hypertension. Meticulous control of diabetes can reverse microalbuminuria and may slow the progression of nephropathy. Blood pressure should be aggressively managed; angiotensin-converting enzyme inhibitors are effective in controlling hypertension and lowering microalbuminuria. Chronic hemodialysis and renal transplantation are unfortunate endpoints for many diabetic patients with renal disease.

Retinopathy

Diabetes is a leading cause of adult blindness in the United States. Approximately 11% to 18% of all diabetic patients have treatable diabetic retinopathy, ranging from mild to severe, and manifested in many forms. The severity of diabetic retinopathy is clearly related to the quality of glycemic control. Background retinopathy is found in most patients with prolonged diabetes and characterized by microaneurysms, small vessel obstruction, cotton wool spots, soft or hard exudates, and macular ischemia. Proliferative retinopathy defines an entity of new vessel formation and scarring, as well as associated vitreal hemorrhage and retinal detachment. The diabetic patient may present with complaints ranging from acute blurring of vision to sudden unilateral or even bilateral blindness. Less often, diabetic patients have more gradual vision loss caused by the common senile cataract (or snowflake cataract), which may disappear as the hyperglycemia is corrected. Diabetic patients with retinopathy should be referred to an ophthalmologist. Even in those with normal vision, ophthalmologic procedures may limit visual loss or prevent crises such as neovascular glaucoma.

Neuropathy

Autonomic and peripheral neuropathies are well-known complications of diabetes. The prevalence of peripheral neuropathy ranges from 15% to 60%. The cause of the neuropathy is not clearly understood, but studies have suggested several factors in its development, including the effects of diabetic vascular disease on the vasa nervorum. Neurologic manifestations of diabetes may regress with improved glycemic control.

Several distinct types of neuropathy have been recognized in diabetes. Peripheral symmetric neuropathy is a slowly progressive, primary sensory disorder manifested bilaterally with anesthesia, hyperesthesia, or pain. The pain is often severe and worse at night. It affects the upper and lower extremities, although the lower extremities and distalmost sections of the involved nerves are most often affected. There may be a motor deficiency as well. The pain may be very difficult to control; opioid analgesics have been used, but nonopioid medications such as gabapentin, pregabalin, and amitriptyline are preferred. Pregabalin is the newest of these agents and seems to hold the most promise when used at higher dosages (up to 600 mg/day). Duloxetine at a dosage of 60 mg/day is also effective. Both pregabalin and duloxetine achieve significant pain control in at least 50% of patients. Gabapentin, 300 mg tid, has some efficacy, achieving significant pain relief in about one-third of patients; amitriptyline 25 mg daily demonstrates similar results. A reasonable approach for the emergency clinician is the initiation of duloxetine or pregabalin, because these have shown the best efficacy in pain control, with the understanding that it may take several days for a peak effect to be reached. Gabapentin in particular has a narrow toxic to therapeutic margin; for many patients, full therapeutic benefits do not occur until the dosage is 600 mg tid or more, at which point sedation frequently becomes severe enough to make the treatment intolerable.

Mononeuropathy, or mononeuropathy multiplex, affects motor and sensory nerves, generally one nerve at a time. The onset is rapid, with wasting and tenderness of the involved muscles. There may be a sudden onset of wrist drop, foot drop, or paralysis of cranial nerves III, IV, and VI. Diabetic truncal mononeuropathy occurs rapidly in a radicular distribution. In contrast to other mononeuropathies, it is primarily if not exclusively sensory. If it causes pain, it may mimic that of a myocardial infarction or acute abdominal inflammation. Like diabetic mononeuropathy, it may be most bothersome at night and generally resolves in a few months. Whereas diabetic mononeuropathy is often the first indication of diabetes, truncal mononeuropathy is more often found in known diabetic patients. Management is similar to other diabetic neuropathies, with the exception of CN III palsy, which is usually expectant management.

Autonomic neuropathy occurs in many forms. Neuropathy of the GI tract, with resultant gastroparesis, is manifested by difficulty in swallowing, delayed gastric emptying, constipation, and/or nocturnal diarrhea. Impotence and bladder dysfunction or paralysis may occur. Orthostatic hypotension, syncope, and even cardiac arrest have resulted from autonomic neuropathy. Diabetic diarrhea responds to diphenoxylate and atropine, loperamide, or clonidine. Orthostatic hypotension is treated by sleeping with the head of the bed elevated, avoidance of sudden standing or sitting, and use of full-length elastic stockings. For gastroparesis, we recommend metoclopramide for its prokinetic and antiemetic properties. Many patients with gastroparesis present with abdominal pain; opioids are not recommended for this group due to the risk of worsening dysmotility of the GI tract.

The Diabetic Foot

Approximately 20% of hospitalizations in diabetic patients are related to foot problems. Sensory neuropathy, ischemia, and infection are the principal contributors to diabetic foot disease. Loss of sensation leads to pressure necrosis from poorly fitting footwear and small wounds going unnoticed. The most common cause of injury is pressure on plantar bone prominences. All neuropathic foot ulcers should be assessed for infection, devitalized tissue débrided, and radiographs obtained to evaluate for the presence of foreign bodies, soft tissue gas, or bone abnormalities.

Not all ulcers are infected. Infection is suggested by local inflammation or crepitation. Conversely, some uninflamed ulcers are associated with underlying osteomyelitis. Most mild infections are caused by gram-positive cocci, such as *Staphylococcus aureus* or streptococci, and may be treated with oral antibiotics with activity against gram-positive organisms, such as trimethoprim-sulfamethoxazole, 800/160 mg bid, a first-generation cephalosporin such as cephalexin, 500 mg qid, or clindamycin, 300 mg qid. A strict non–weight-bearing regimen, meticulous wound care, and daily follow-up are also vitally important to wound healing.
This approach may not be possible when patients are deemed unreliable, do not have good home support, or do not have ready access to follow-up care.

Deeper, limb-threatening infections—as evidenced by full-thickness ulceration, cellulitis more than 2 cm in diameter, with or without lymphangitis, bone or joint involvement, or systemic toxicity—are usually polymicrobial in origin and caused by aerobic gram-positive cocci, gram-negative bacilli, and anaerobes. These patients require hospitalization and, after culture, broad-spectrum IV empirical antimicrobial therapy (Table 118.3), strict non-weight-bearing status, tight glycemic control, early surgical intervention for débridement, and meticulous wound care. Occult osteomyelitis should be considered in all cases of neuropathic ulceration. Hyperbaric oxygen has been shown to have some efficacy in the treatment of complicated infection, especially with anaerobic organisms. Up to one-third of patients eventually undergo amputation.

### Infections

Diabetic patients are more susceptible to complications of infections because of their inability to limit microbial invasion with effective polymorphonuclear leukocytes and lymphocytes. They have an increased incidence of extremity infections and pyelonephritis compared with the general population. In addition, they are particularly susceptible to certain other infections, such as tuberculosis, mucocutaneous candidiasis, intertrigo, mucormycosis, soft tissue infections, nonclostridial gas gangrene, osteomyelitis, and malignant *Pseudomonas* otitis externa (Table 118.4); glycemic control and generally hospitalization are recommended.

### Cutaneous Manifestations

Dermal hypersensitivity is manifested by pruritic erythematous indurations that occur at insulin injection sites. The declining prevalence of this condition has paralleled the improved purification of insulin. Similarly, insulin lipodystrophy seems to be a result of insulin impurities and is manifested as subcutaneous depres-

This is evidence of the hyperlipidemia associated with diabetes. It is similar to the xanthoma.

### Skin Conditions

Diabetic skin conditions include fungal infections, acanthosis nigricans, necrobiosis lipoidica diabeticorum, xanthoma diabeticorum, bullous diabeticorum, and diabetic dermopathy.

**Acanthosis Nigricans.** This is characterized by a velvety, brown-black thickening of the keratin layer, most often in the flexor surfaces. It is the cutaneous marker for a group of endocrine disorders with insulin resistance.

**Necrobiosis Lipoidica Diabeticorum.** This begins as erythematous papular or nodular lesions, usually in the pretibial area but in other areas as well. The early lesions may contain telangiectasias. These lesions spread and frequently form a single pigmented area of atrophic skin, often with a yellow and sometimes ulcerated center and an erythematous margin. A history of previous trauma is sometimes found.

**Xanthoma Diabeticorum.** This is evidence of the hyperlipidemia associated with diabetes. It is similar to the xanthoma.
found in nondiabetic hyperlipidemic patients. Xanthomas have an erythematous base and a yellowish hue.

**Bullae Diabeticorum.** This is a rare occurrence. Bullae are usually filled with a clear fluid and are most often found on the extremities, especially the feet. The fluid is occasionally slightly hemorrhagic. The bullae usually heal spontaneously, without scarring.

**Diabetic Dermopathy.** Also known as skin spots, this is the most common finding in diabetes. It arises as discrete, depressed, and brownish lesions generally less than 15 mm in diameter and found in the pretibial area.

**Impetigo or Intertrigo.** Resistant, aggressive impetigo or intertrigo suggests diabetes.

### DIABETES IN PREGNANCY

Before the discovery of insulin in 1922, diabetes in pregnancy was associated with a fetal death rate of 60% to 72% and maternal morbidity of approximately 30%. In 1977, a linear relationship between glycemic control and perinatal mortality was discovered. Strict metabolic control is now a goal in all diabetic pregnancies.

Pregnant patients should be watched extremely closely and aggressively treated for impending or actual DKA. For a variety of reasons, pregnant women have a special predisposition to glucose intolerance and excess ketone production. Although uncommon, DKA may reduce fetal oxygen delivery and cause perinatal asphyxia. Intellectual deficits in the offspring have been associated with maternal ketonuria from any cause.

Hypoglycemia is common in pregnancy, in part because of intensive insulin treatment to maintain euglycemia. The effects of hypoglycemia on the fetus are unclear. Severe ketoacidosis is associated with a 50% to 90% fetal mortality rate due to hypoperfusion of the placenta.

### HYPOGLYCEMIA

#### Principles

Hypoglycemia is a common problem in patients with type 1 diabetes, especially if tight glycemic control is practiced; it is the most dangerous acute complication of diabetes. The estimated incidence of hypoglycemia in diabetic patients is 9 to 120 episodes/100 patient-years. As significant efforts continue to keep fasting and postprandial glucose concentrations within the normal range, the incidence of hypoglycemia may increase. The most common cause of coma associated with diabetes is an excess of administered insulin with respect to glucose intake. Severe hypoglycemia is usually associated with blood glucose levels below 40 to 50 mg/dL and impaired cognitive function.

Protection against hypoglycemia is normally provided by cessation of insulin release and mobilization of counterregulatory hormones, which increase hepatic glucose production and decrease glucose use. Diabetic patients using insulin are vulnerable to hypoglycemia because of insulin excess and failure of the counterregulatory system.

Hypoglycemia has many causes, such as missing a meal (decreased intake), increased energy output (exercise), and increased insulin dosage. It can also occur in the absence of any precipitant. Oral hypoglycemic agents have also been implicated in causing hypoglycemia, both during the course of therapy and as an agent of overdose.

Hypoglycemia without warning symptoms, or hypoglycemia unawareness, is a dangerous complication of type 1 diabetes and is probably caused by previous exposure to low blood glucose concentrations, because even a single hypoglycemic episode can reduce neurohumoral counterregulatory responses to subsequent episodes. Other factors associated with recurrent hypoglycemic attacks include overaggressive or intensified insulin therapy, longer history of diabetes, autonomic neuropathy, and decreased epinephrine secretion or sensitivity.

The Somogyi phenomenon is a common problem associated with iatrogenic hypoglycemia in the type 1 diabetic patient. The phenomenon is initiated by excessive insulin dosing, resulting in an unrecognized hypoglycemic episode that usually occurs in the early morning while the patient is sleeping. The counterregulatory hormone response produces rebound hyperglycemia, evident when the patient awakens. Often, the patient and physician interpret this hyperglycemia as an indication to increase the insulin dosage, which exacerbates the problem. Instead, the insulin dosage should be lowered or the timing changed.

#### Clinical Features

Symptomatic hypoglycemia occurs in most adults below a blood glucose level of 40 to 50 mg/dL. The rate at which the glucose level decreases, however, and the patient’s age, gender, size, overall health, and previous hypoglycemic reactions contribute to symptom development. Signs and symptoms of hypoglycemia are caused by excessive secretion of epinephrine and CNS dysfunction; these include sweating, nervousness, tremor, tachycardia, hunger, and neurologic symptoms, ranging from bizarre behavior and confusion to seizures and coma. In patients with hypoglycemia unawareness, the prodrome to marked hypoglycemia may be minimal or absent, and these individuals may rapidly become unarousable. They may have a seizure or show focal neurologic signs, which resolve with glucose administration.

#### Differential Diagnoses

Hypoglycemia in the nondiabetic patient may be classified as postprandial or fasting. The most common cause of postprandial hypoglycemia is alimentary hyperinsulinism, such as that seen in patients who have undergone gastrectomy, gastrojejunostomy, pyloroplasty, or vagotomy. Fasting hypoglycemia is caused when there is an imbalance between glucose production and use. The causes of inadequate glucose production include hormone deficiencies, enzyme defects, substrate deficiencies, severe liver disease, and drugs. Causes of overuse of glucose include the presence of an insulinoma, exogenous insulin, sulfonylureas, drugs, endotoxic shock, extrapancreatic tumors, and a variety of enzyme deficiencies.

#### Diagnostic Testing

The cardinal laboratory test for hypoglycemia is determination of the blood glucose concentration. It should be performed, if possible, before therapy is begun. As noted, fingerstick readings are helpful in permitting rapid, reasonably accurate blood glucose level estimates before therapy.

Laboratory testing should address any suggested cause of the hypoglycemia, such as ethanol or other drug ingestion. If factitious hypoglycemia is suggested, testing for insulin antibodies or low levels of C peptide may be helpful. A patient who is surreptitiously administering exogenous insulin will have normal to low levels of C peptide and markedly elevated insulin levels.

#### Management

In alert patients with mild symptoms, oral consumption of sugar-containing foods or beverages is often adequate. In other patients, after blood is drawn for glucose determination, one to three ampules of D₅₀W is administered IV while the patient’s airway, breathing, and circulation are assessed and maintained.
Augmentation of the blood glucose level by administration of an ampule of D_{50}W may range from less than 40 mg/dL to more than 350 mg/dL. If alcohol abuse is suggested, thiamine is administered. In children younger than 8 years, providers should use D_{25}W or D_{35}W. D_{25}W may be prepared by diluting D_{50}W 1:1 with sterile water. The dose is 0.5 to 1 g/kg body weight or 2 to 4 mL/kg when using D_{35}W.

If IV access cannot be rapidly obtained, 1 to 2 mg of glucagon may be given intramuscularly or subcutaneously. The onset of action is 10 to 20 minutes, and a peak response occurs in 30 to 60 minutes. It may be repeated as needed. Glucagon may also be administered IV; 1 mg has an effect similar to that of one ampule of D_{50}W. Glucagon is ineffective in causes of hypoglycemia in which glycogen is absent, notably alcohol-induced hypoglycemia.

Families of type 1 diabetic patients are often taught to administer glucagon intramuscularly at home. Of the families so instructed, only 9% to 42% actually inject the glucagon when indicated. Intranasal glucagon has not been widely used. All patients with severe hypoglycemic reactions require aspiration and seizure precautions. Although the response to IV administration of glucose is generally rapid, older patients may require several days for complete recovery.

Treatment of hypoglycemia secondary to oral hypoglycemic agents depends on the agent. Metformin and the thiazolidinediones rarely cause significant or prolonged hypoglycemia, whereas sulfonylureas, which are insulin secretagogues, do cause hypoglycemia. Sulfonylurea oral hypoglycemic agents pose special problems because the hypoglycemia they induce tends to be prolonged and severe. Patients with an overdose of sulfonylurea hypoglycemic agents should be observed for a period of 24 hours if hypoglycemia recurs in the ED after management of the initial episode. Patients at risk for hypoglycemia from oral sulfonylureas include patients with impaired renal function, pediatric patients, and patients who are naïve to hypoglycemic agents. Although symptoms may occur after an overdose, several case reports in patients (eg, with renal failure and pediatric patients) have described refractory hypoglycemia after ingestion of a single pill. One case series of pediatric patients presenting with sulfonylurea ingestion who were euglycemic initially demonstrated an average time to onset of 8 hours to the initial hypoglycemic episode. However, in some patients, onset of symptoms was delayed for up to 18 hours. As a result, we recommend 24 hours of observation for patients with known or suspected ingestion of hypoglycemic agents.

A patient with hypoglycemia from sulfonylureas, in addition to standard glucose replacement, frequently requires treatment with an agent to inhibit further insulin release, such as octreotide, a somatostatin analogue. Several case series have described the use of octreotide in adult and pediatric patients suffering from sulfonylurea-induced hypoglycemia, frequently reporting successful results, with a significant decrease in the number of episodes of recurrent hypoglycemia. A randomized clinical trial has concluded that patients receiving octreotide had a decreased glucose supplementation requirement. No single set protocol for use has been described; however, typical adult doses have ranged from 50 to 100 µg IV or subcutaneously every 12 hours, with pediatric dosages of 0.1 mcg/kg IV or subcutaneously. Although experience thus far with octreotide has been positive, it does not obviate the need for prolonged observation and serial glucose level measurements.

Disposition

Type 1 diabetic patients with brief episodes of hypoglycemia uncomplicated by other disease may be discharged from the ED if a cause of the hypoglycemia can be identified and corrected by instruction or medication. All patients should be given a meal before discharge to ensure their ability to tolerate oral feedings and to begin to replenish glycogen stores in glycogen-deficient patients. Patients who are discharged should receive short-term follow-up for ongoing evaluation. Patients with hypoglycemia caused by long-acting sulfonylurea medications should be observed in the hospital if they have recurrent hypoglycemia after a period of observation in the ED. Other agents, such as metformin, do not typically produce hypoglycemia, although they may have other issues, such as lactic acidosis, that may require admission.

The determination of inpatient versus outpatient evaluation of hypoglycemia in a nondiabetic patient should be based on the suggested cause and nature of the episode (ie, factors such as severity, persistence, and recurrence).

**KEY CONCEPTS**

- The diagnosis of diabetes can be determined by one or more of four methods—random plasma glucose level above 200 mg/dL, fasting plasma glucose concentration above 126 mg/dL, 2-hour, 75-g postload OGT > 200 mg/dL, or HbA_{1c} value above 6.5%.
- DKA is diagnosed by the presence of hyperglycemia, anion gap metabolic acidosis, and elevated ketoad levels.
- The essential treatment of DKA includes restoration of insulin, correction of dehydration, correction of potassium level, correction of acidosis, and treatment of the underlying cause.
- Use of sodium bicarbonate to correct acidosis in DKA has not demonstrated any benefit and may be associated with worse outcomes.
- A hyperglycemic hyperosmolar state is usually seen in older adults with multiple comorbid conditions and is distinguished from DKA by the absence of ketoacidosis. In addition to fluid resuscitation and correction of hyperglycemia, treatment should address the underlying cause of the state, which includes infection, myocardial infarction, and cerebrovascular accident.
- Diabetic peripheral neuropathy is common and has multiple treatment modalities, including gabapentin, pregabalin, and duloxetine.
- Diabetic foot ulcers and other diabetic soft tissue infections (eg, gas gangrene, fourier’s gangrene) are frequently polymicrobial and require broad-spectrum antibiotic therapy covering gram-positives, gram-negatives, and anaerobes.
- Hypoglycemia may be associated with significant morbiditly and mortality. When the diagnosis is suggested and, if possible, confirmed by laboratory evaluation, therapy should be initiated immediately.
- Hypoglycemia caused by sulfonylurea oral hypoglycemic agents may be prolonged. Patients should be observed for an extended period or hospitalized.

CHAPTER 118: QUESTIONS & ANSWERS

118.1. Which of the following statements regarding patients with impaired glucose tolerance is true?
A. Spontaneous reversion to normal glucose tolerance is rare.
B. The condition is associated with fewer complications than diabetes mellitus.
C. The rate of decompensation to diabetes mellitus is greater than 10%/year.
D. There is a predisposition to ketosis.
E. There is no increased risk of cardiovascular complications.

Answer: B. Patients with impaired glucose tolerance have a glucose level between normal and diabetic. They are at increased risk of cardiovascular disease and development of diabetes (1%-5%/year), but it is not associated with the same degree of complications as with true diabetes. Many patients spontaneously develop normal glucose levels.

118.2. What percentage of adults with type 2 diabetes are obese?
A. 20%
B. 40%
C. 60%
D. 80%
E. 100%
